Modifying TiO₂ Nanoparticles by Atomic Layer Deposition for Enhanced Photocatalytic Water Purification

Dissertation

for the purpose of obtaining the degree of doctor
at Delft University of Technology
by the authority of the Rector Magnificus, prof. dr. ir. T.H.J.J. van der Hagen
Chair of the Board of Doctorates

To be defended publicly on
4th September, 2020 at 12:30

By

Dominik BENZ

Master of Science in Molecular Science,
Friedrich-Alexander University of Erlangen-Nuremberg, Germany
Born in Roth, Germany

This dissertation has been approved by the promotor.

Composition of the doctoral committee:

Rector Magnificus,	chairperson
Prof. Dr. ir. J. R. van Ommen	Delft University of Technology, promotor
Prof. Dr. ir. M. T. Kreuzer	Delft University of Technology, promotor
Dr. H. T. J. M. Hintzen	Delft University of Technology, copromotor

Independent members:

Prof. Dr. ir. L. C. Rietveld	Delft University of Technology
Prof. Dr. B. Dam	Delft University of Technology
Prof. Dr. ir. S. Verbruggen	University of Antwerp
Prof. Dr. J. Bachmann	Friedrich-Alexander University of Erlangen-Nuremberg

Science for the benefit of people. All people. Worldwide.

This research was supported by the TU Delft | Global Initiative, a program of the Delft University of Technology to boost Science and Technology for Global Development.

Keywords: photocatalysis, water cleaning, TiO₂, nanoparticles, atomic layer deposition

Introduction

1.1. THE WATER PROBLEM IN DEVELOPING COUNTRIES

Water – the most abundant resource on earth yet freshwater is so scarce. Billions of people are condemned to only have access to polluted water sources, which causes diseases and death. ¹ Many scientists and politicians predict that future wars will not be fought over land or oil but over clean water, which indicates the high importance of this topic. ²⁻³ Clean drinking water is one of the significant challenges humankind is facing nowadays all around the world and is therefore legitimately represented as one of the UN sustainable development goals (SDG 6: Clean Drinking water and sanitation). The specific target 6.1 describes the aim to provide universal and equitable access to safe and affordable drinking water for all by 2030. ¹

Figure 1.1: Pollution in the River Sông Nhuệ in Hanoi, Vietnam; photo taken during a research stay in Vietnam (Sept. 2019).

Especially the situation in developing countries is alarming where access to clean drinking water is a luxury, and water bodies are often used as an easy cheap solution for waste discharge resulting in massive contamination of both solids and dissolved contaminants. However, conventional water treatment technologies require complex infrastructure and significant financial investments. Especially in more remote areas, this is not feasible, and other solutions might be better suitable for the needs. Ideally, in those cases, a treatment technology can be operated with little reliance on the power grid and is reliable in remote areas. That means that maintenance should be limited and easily manageable.

Conventional water treatment technologies rely on multistep treatments where sieving, filtration, and bacterial treatment for very polluted sources is applied to ensure high-quality drinking water. Those conventional steps to clean water are cost and equipment intensive technologies. Especially adsorption technology to filter micropollutants from

the water only binds the pollutants on the active surface to separate it from the water, which makes refurbishing of the filters needed after they reached their maximum capacity. A cheaper technology, which does not separate but degrades the pollutants from the water into non-toxic compounds, would be therefore preferred.

1.2. HETEROGENEOUS PHOTOCATALYSIS FOR WATER TREATMENT

As an alternative approach to conventional water treatment, photocatalysis has developed over the last decades as a promising technology that uses the light, e.g., sunlight or artificial light sources, to generate active species which are able to degrade the organic pollutants in the water. ⁴⁻⁶

1.2.1. Fundamentals

In heterogeneous photocatalysis, a solid material serves as a catalytic surface to transform chemicals into degradation products. Different from conventional thermal catalysis, the material is activated by light, which provides the energy to convert chemicals into other compounds. ⁷ For water treatment, organic molecules are degraded via redox reactions ideally to CO_2 and H_2O , leaving little trace behind in the water. Photocatalytic materials are usually semiconductors having a bandgap that separates the valence band (VB), which in the ground state is filled with electrons, and the empty conduction band (CB).

Figure 1.2: Scheme of the photocatalytic mechanisms to degrade organic pollutants in water. ⁸

In particular, as illustrated in Figure 1.2, upon light excitation (1), an electron (e⁻) is transferred from the VB to the CB (2), gaining the energy of the absorbed photon. After excitation, the generated electrons and holes (h⁺) will transfer to the surface (3a) or

suffer undesired charge recombination losing the potential to facilitate relevant redox reactions. Possible charge recombination (3b) can be minimized by electron-hole pair separation (e.g., by combining with a second material). If the band level of the CB is higher than the reduction potential of O_2 the high energy electron in the CB is able to reduce dissolved oxygen in the water (4a) to a superoxide radical ($O_2^{\cdot-}$) which subsequently reacts to a hydroxyl radical (OH^{\cdot}) degrading the organic pollutant. On the other hand, upon excitation of an electron, a hole resides in the VB. This hole can contribute in two ways to pollutant degradation: firstly, the hole can react with water to form OH^{\cdot} radicals, which subsequently degrade the organic pollutant (4b) or, secondly, with the pollutant, oxidizing it directly resulting in the degradation of the molecule (4c). This gives three different pathways to degrade organic pollutants: 1) via OH^{\cdot} radicals formed from superoxide $O_2^{\cdot-}$ radicals by excited electrons in the CB pathway, 2) via OH^{\cdot} radicals generated by the hole, and 3) direct oxidation of the pollutant by the hole both in the VB pathway. Often the generation of radicals from electrons or holes is summarized as the generation of reactive oxygen species (ROS).

1.2.2. Parameters influencing the photocatalytic activity

Despite the enormous potential of using sunlight to degrade organic pollutants, the development of photocatalysis has not reached a state yet to implement this technology on an industrial scale. After decades of research, photocatalysis is still facing challenges caused by low efficiencies in catalyst materials.^{9 6}

Table 1.1: Influence of a) process parameters and b) material properties on the photocatalytic activity, “positive” indicates with increase of the parameter/property the activity increases, “negative” indicates with increase of the parameter/property the activity decreases, “optimal” indicates this parameter has an optimal value for the highest photocatalytic activity.

a) Process parameters	Influence on activity
Temperature	Negligible ^{4, 10}
Dissolved Oxygen	Positive ¹¹⁻¹²
Catalyst concentration	Optimal ¹³⁻¹⁴
Mixing	Positive ¹³
Pollutant concentration	Negative ¹⁵
pH	Dependent on catalyst ¹⁶
Light intensity	Positive ¹⁷⁻¹⁸
b) Material properties	Influence on activity
Surface area	Positive ¹⁹
Surface charge	Pollutant dependent ²⁰⁻²¹
Bandgap	Negative ²²⁻²³ (also dependent band levels and radiation source)
Charge carrier lifetime	Positive ²⁴⁻²⁵
Surface reactivity	Positive ²⁶⁻²⁷

Many different parameters are influencing the photocatalytic activity of a material.^{5,9} On the one hand, process parameters such as temperature, dissolved oxygen concentration, catalyst concentration, mixing (mass transfer), pollutant concentration, pH, and light intensity generally affect the photocatalytic activity (Table 1.1a).

However, external process parameters are usually predefined for a particular environment and need to be taken into account for the catalyst development. On the other hand, material properties (Table 1.1b) such as surface area, bandgap, charge carrier kinetics and surface functionalities for ROS generation give the intrinsic activity of the catalyst material that is directly related to the prevalent mechanistic steps during the photocatalytic degradation:

- 1) Adsorption of reactants (pollutant or ROS educts)
- 2) Light absorption resulting in electron-hole pairs
- 3) Generation of active species by oxidation/reduction reactions
- 4) Desorption of reactants (degraded pollutants or ROS)

1.2.3. TiO₂ (P25) as benchmark photocatalyst

TiO₂ is one of the most often used photocatalysts and often serves as a benchmark for new developments because of its stability, non-toxicity, low costs, and good performance.^{9,28} A particular type of TiO₂ is P25. This purely TiO₂ based material consists of nanoparticles (mean primary particle size approx. 21 nm)²⁹ with mixed crystalline phases of anatase (~80 %) and rutile (~20 %). With a large bandgap of about 3.0 eV for the rutile and 3.2 eV for anatase phase, P25 absorbs light with a wavelength lower than 410 nm.⁷ However, due to this large bandgap, P25 suffers poor sunlight absorption just in the UV range, which hampers the application under solar light. Additionally, mechanistic insights state that rapid charge recombination keeps the efficiency too low for implementation in real water treatment using solar light.⁶ Therefore, from the discovery of TiO₂ as a photocatalyst, a lot of effort was dedicated to improving the photocatalytic efficiency using modifications.

1.2.4. Modification and improvement possibilities

Several strategies arise to modify a catalytic material in order to improve the activity by reducing limiting factors for the catalyst in the photocatalytic mechanism. Each of the above-mentioned steps of the photocatalytic pathway may be subject to improvement, starting from the light absorption and charge separation to then generation of radical oxygen species (ROS). Furthermore, the adsorption of reactants, both pollutants, and precursors for the ROS generation, may increase the overall activity of the photocatalyst as it increases the local concentration close to the catalyst surface. Apart from those intrinsic photocatalytic properties, especially the surface area

and for powders additionally the dispersibility, which influences the accessible surface area due to agglomeration, are essential parameters.

Figure 1.3: Modification possibilities of base photocatalysts to improve the overall reaction rate: A) optimizing the reactant adsorption by modifying the surface charge with the deposition of a thin layer, B) improving the light absorption by decreasing the bandgap employing bulk doping, C) modifying the surface by adding clusters of a second material on the surface to enhance the charge separation in order to prevent charge recombination, D) modifying the surface by depositing a thin layer of a second material to enhance the reactivity on the surface.

In principle, three strategies arise to modify the intrinsic activity of a catalyst – 1) bulk doping, incorporating heteroatom in the structure of the material, 2) surface modification, adding functionalities on the surface, and 3) modification of the surface morphology/crystal structure.

In order to improve the light absorption, usually, bulk doping is applied to influence the band structure shifting the light absorption to longer wavelength (Fig. 1.3 b).²²⁻²³ Minute surface modifications, on the other hand, can give an improvement in the reactant adsorption²¹, charge carrier kinetics²⁵, and surface reactivity (Fig. 1.3)²⁶. In order to enhance the adsorption of the reactants, the surface properties may be changed by adding a thin layer of material to modify the surface charge (Fig 1.3 a). Furthermore, charge recombination is an important factor limiting the photocatalytic activity. Adding different materials can facilitate charge separation, where the distinct band levels allow spatial separation of an electron from the hole (Fig. 1.3 c).²⁴⁻²⁵ This increases the lifetime of the electron and hole, enabling an efficient transfer to the reactants and more probable reaction. In order to improve the surface reactivity, materials with a high number of functional groups, i.e. M–OH groups, may be deposited to increase the ROS generation (Fig. 1.3 d).²⁶⁻²⁷ Thirdly, modifying the crystal structure or surface morphology will influence these parameters and are commonly used to improve the photocatalytic activity. However, the aim to improve the photocatalytic activity of an already prepared crystalline material such as TiO₂ (P25) nanoparticles only make modifications at the surface feasible and accessible. This approach of surface modification excludes, therefore, modifying the bandgap but enables the changes in the reactant adsorption, charge carrier separation, and surface reactivity. In recent years research efforts have been mainly focused on the reduction of the

charge recombination and the development of visible light absorbing photocatalysts. Substantial steps have been made to improve the photocatalytic activity. Despite these improvements in photocatalytic activity especially by tuning visible light activity and suppression of charge recombination, the lack of implementation into real applications shows that the technology of cleaning water using photocatalysis still faces challenges both on a fundamental and application level.³⁰

1.3. SURFACE MODIFICATION OF PHOTOCATALYSTS BY ATOMIC LAYER DEPOSITION

1.3.1. Fundamentals

Atomic Layer Deposition (ALD) belongs to the family of chemical vapor deposition techniques where vaporized chemicals react at the surface to build-up materials. ALD relies on the principle of self-limiting surface reaction, where two or more reactants are introduced to the surface separately. Figure 1.4 describes a detailed scheme on the four general ALD steps on the example of the growth of SiO_2 layers on the TiO_2 surface.

Figure 1.4: Scheme of the four steps of an ALD cycle to deposit layers of, e.g. SiO_2 on a metal oxide surface, A) Precursor pulse SiCl_4 , B) Purge with inert gas, C) Oxidizer pulse H_2O , D) Purge with inert gas. (Si = orange sphere, Cl = green sphere, O = red sphere, H = white sphere).

In detail, in the first step, SiCl_4 reacts with the M-OH groups commonly present at the metal oxide surface, resulting in a chemisorbed Si-Cl group until no OH group remains on the surface or is not accessible anymore due to steric hindrance. In a second step, the excess precursor (i.e., SiCl_4) and formed by-products (i.e., HCl) are purged out of the reaction chamber by an inert gas. In order to refresh the surface with -OH groups, the counter-reactant (i.e., H_2O) is introduced to the reaction chamber to react with the terminal Si-Cl groups resulting in the terminal Si-OH groups. The counter-reactant pulse is again followed by a purging step to flush left-over precursor and by-products out of the system. This last purging step concludes one ALD cycle. Adding various cycles ideally changes the amount of material proportionally. The deposition of metals using ALD usually occurs via the combustion of the ligands by strong oxidizers such as O_3 .³¹⁻³²

Dependent on the surface properties of the substrate and the molecule affinity towards the surface, different structures may arise – a high affinity of the deposited material towards the surface leads to full coverage of the substrate resulting in layers or a low affinity/high surface energy of the deposited material leads to the formation of particles. The versatility of ALD gives the opportunity to deposit many different materials, which establishes it as a powerful tool for surface modification and (photo)catalyst development concisely reviewed by O'Neill et al.³³

1.3.2. Benefits of ALD for photocatalyst development

Catalytic activity strongly depends on various structural factors in a material – crystallinity²⁰, surface area & morphology^{19, 34} of a material and especially even minute addition of material both as overcoating³⁵ and as nanoclusters³⁶. This implies that in order to meet those requirements of precise surface tunability, ALD serves as a very suitable technique. Especially for the addition of material while sustaining the photocatalytic activity of the base materials, only very subtle modifications may be induced to the surface, such as deposition of very thin/porous layers or nanoclusters. The self-limiting behavior allows depositing materials on a substrate in a very defined manner being able to tune the material properties precisely. It further allows (dependent on the substrate and the deposited material's surface energy) to either overcoat a material³⁷ or deposit nanoclusters³⁸ on the surface, which gives an additional degree of surface modification. Dependent on the process parameters such as deposition temperature or pulse time also the cluster size and size distribution can accurately be tuned as shown in previous research³⁹, which significantly influences the catalytic properties⁴⁰⁻⁴¹. Furthermore, as a gas phase deposition, the use of solvents is redundant. Apart from the environmental factor, the degree of contamination due to a solvent can be minimized. Last but certainly not least, the scalable approach using ALD in a fluidized bed at atmospheric pressure gives additionally the chance to produce more copious amounts⁴² to meet eventual needs for the implementation in a photoreactor.

1.4. FRAMEWORK OF THIS THESIS AND RESEARCH QUESTIONS

This project was initiated in the framework of the Delft | Global Initiative, a program that supports global development by tackling rising problems in developing countries. In that regard, this project was aiming at the combination of catalyst design with reactor engineering to develop a smart solution for water purification in low resource countries.

For the development of a photocatalytic system to purify water, several steps need to be tackled. An efficient catalyst needs to be developed by smart modification of the surface combined with carefully analyzing the mechanisms behind the improved photocatalytic activity. This analysis will set the framework on the working conditions of the catalyst. The working conditions greatly influence the design of the photoreactor where mass transport, light distribution, and kinetic reaction rate limitations need to be optimized. It is crucial to iterate between catalyst design and reactor design since, e.g. an improvement in the activity of the catalyst would be redundant if the mass transfer would limit the efficiency of the system. Therefore, only after developing a photocatalyst in agreement with a suitable reactor, a next step can be taken towards implementation. The relationships between these different aspects are schematically represented in Fig. 1.5.

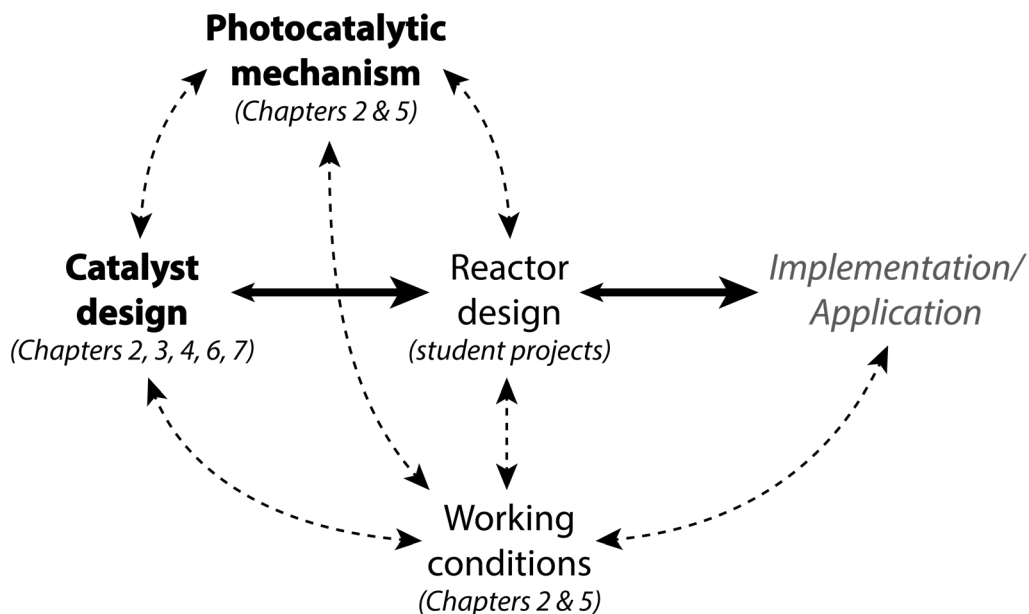

Figure 1.5: Framework of this thesis in the picture of the development and application of a photoreactor to clean water. Arrows indicate relationships between the main topics covered in this thesis (bold characters), topics excluded from this thesis but accessible in various student theses from our group on related topics (regular characters), research not addressed in this thesis (italic characters). Dashed arrows represent the subjects influencing the primary steps towards implementation, catalyst design, and reactor design.

Specifically, the primary goal of this research was to improve the photocatalytic activity of TiO₂ nanopowder (P25) by surface modification using atomic layer deposition and secondly to design a suitable reactor for the cleaning of water. However, after an initial assessment of this project proposal, the focus shifted to material improvement combined with mechanistic studies rather than the complete path to implementation in a photoreactor.

Therefore, this thesis will deal with the main research question,

How can we modify the surface of TiO₂ (P25) using ALD to improve its photocatalytic activity to purify water?

and the following sub-questions:

- 1) Is it possible to use cheaper materials than the commonly used noble metals to improve the photocatalytic activity of TiO₂ (P25)?
- 2) How do ALD surface modifications affect the photocatalytic mechanism of the modified material compared to TiO₂ (P25)?
- 3) Using the understanding of how surface modifications improve the photocatalytic activity of TiO₂ (P25), is it possible to combine multiple modifications in one material to design better multicomponent photocatalysts?

1.5. OUTLINE

In this thesis, six experimental chapters (Chapter 2 - 7) are accompanied by an introduction to photocatalysis for water treatment and atomic layer deposition (Chapter 1), and a conclusion chapter with an outlook on the approach investigated in this Ph.D. thesis and future feasibility of applying photocatalysis for water purification as a low-cost technology to provide clean drinking water (Chapter 8). All scientific chapters are (or will be) submitted to peer-reviewed international journals.

Chapter 2 tackles the unresolved mechanism of the improvement due to Pt clusters on TiO₂ (P25) in the photocatalytic activity of dye degradation. The combination of several characterization methods looking into both the physical and the photochemical properties of Pt:TiO₂(P25) gives a broad picture of the processes during the photocatalytic degradation. Especially the degradation under different atmospheres reveals the importance of dissolved O₂ for the different materials – TiO₂(P25) and Pt:TiO₂(P25).

Chapter 3 describes the new development of depositing Cu₂O clusters on TiO₂(P25) using atomic layer deposition in a fluidized bed at atmospheric pressure. The Cu₂O:TiO₂(P25) system was chosen to enhance the charge separation due to the

beneficial band level arrangements of Cu_2O with TiO_2 (P25). This system demonstrated low loadings of Cu_2O enhance the photocatalytic activity for various pollutants.

Chapter 4 deals with the deposition of ultrathin SiO_2 layers on TiO_2 (P25) nanoparticles using ALD. Layers of various thicknesses were deposited, which showed an optimum in the photocatalytic degradation of Rhodamine B. The mechanism for this improvement is further investigated in the following chapter.

Chapter 5 investigates how ultrathin SiO_2 layers on TiO_2 (P25) improve the photocatalytic activity by revealing the photocatalytic mechanism of this low-cost modification with SiO_2 on TiO_2 (P25). Various characterization techniques, including scavenging agents, were used to evaluate the contribution of different steps in the photocatalytic mechanism of degradation of two dyes with opposite charge. The results indicate a change of the mechanism from direct oxidation for TiO_2 (P25) to a more hydroxyl radical based degradation.

Chapter 6 takes the results of Chapters 2, 4, and 5 to design a photocatalyst that uses both improvement strategies into one material. SiO_2 is deposited in layers first on TiO_2 (P25) particles, followed by the deposition of Pt clusters. This Pt: SiO_2 : TiO_2 combination exceeds the photocatalytic activity of both single modified materials SiO_2 : TiO_2 (P25) and Pt: TiO_2 (P25) indicating a smart catalyst design leads to an even further improved photocatalytic activity.

Chapter 7 shows the first time deposition of Au clusters via ALD in a fluidized bed at atmospheric pressure onto TiO_2 (P25) particles. We could show that different ALD parameters such as cycle number, but more importantly, pulse time influence the particle size distribution. Both the loading and the especially the Au particle size strongly influence the photocatalytic activity for the degradation of Acid Blue 9, where specifically smaller Au clusters improve the photocatalytic degradation.

Assessing the role of Pt clusters on TiO₂ (P25) on the photocatalytic degradation of Acid Blue 9 and Rhodamine B

2

The role of Pt on photocatalytic substrates such as TiO₂ (P25) for the decomposition of organic pollutants is still controversial in the scientific community. The well-observed behavior of an optimum catalytic activity as a function of the Pt loading is usually explained by the shift from charge separation to charge recombination behavior of Pt clusters. However, experiments supporting this explanation are still lacking to give a concise understanding of the effect of Pt on the photocatalytic activity. Here, we present an experimental study that tries to discriminate the different effects influencing the photocatalytic activity. Using atomic layer deposition (ALD) in a fluidized bed reactor, we prepared TiO₂ (P25) samples with Pt loadings ranging from 0.04 wt. % to around 3 wt. %. In order to reveal the mechanism behind the photocatalytic behavior of Pt on TiO₂ (P25), we investigated the different aspects (i.e., surface area, reactant adsorption, light absorption, charge transfer, reaction pathway) of heterogeneous photocatalysis individually. In contrast to the often proposed prolonged life-time of charge carriers in Pt loaded TiO₂, we found that after collecting the excited electrons, Pt acts more as a recombination center independent of the amount of Pt deposited. Only when dissolved O₂ is present in the solution, charge recombination is suppressed by the subsequential consumption of electrons at the surface of the Pt clusters with the dissolved O₂ benefited by the improved O₂ adsorption on the Pt surface.

2.1. INTRODUCTION

Photocatalysis to clean water is a promising technology for tackling the rising problem of water pollution, especially in low resource countries. Using materials such as TiO₂ and sunlight, many reports have shown the degradation of a range of pollutants in water.¹⁻⁶ However, the implementation in real-life remains challenging because of a lack of efficiency. Getting insight into the working principles of the developed catalyst will especially help further developments such as combining materials in order to make even more active catalysts. In order to degrade organic pollutants using photocatalysis, generally, four steps take place:⁷⁻⁸

- 1) Adsorption of the reactants (pollutant, O₂, H₂O) on the surface
- 2) Light absorption and generation of charge carriers (e⁻/h⁺)
- 3) Redox reaction on the surface creating hydroxyl radicals, superoxide radicals or directly oxidizing the pollutant
- 4) Desorption of products from the surface

Upon light excitation of the photocatalysts, an electron (e⁻) is excited to the conduction band (CB), leaving a hole (h⁺) in the valence band (VB). Those excited charges generate reactive oxygen species (ROS) such as superoxide radicals (O₂^{•-}) from e⁻_{CB} and hydroxyl radicals (OH[•]) from h⁺_{VB}. However, excited electrons are prone to recombine with holes, if not harvested efficiently, losing the potential for the preferred redox reaction to degrade organic pollutants.

According to this mechanism for the photocatalytic degradation of organic pollutants, three different events lead to the degradation of the pollutant^{4, 9}:

- 1) The creation of superoxide radicals (O₂^{•-}) from the CB electrons and dissolved oxygen leads to the formation of OH[•] radicals which oxidize the pollutant subsequently to CO₂ and H₂O:

- 2) The creation of OH[•] radicals from the reaction of H₂O or -OH groups at the surface with the VB holes which subsequently oxidize the pollutant:

- 3) Generated holes in the VB directly oxidize the pollutant:

In order to improve the performance of a photocatalyst, several approaches are generally proposed: 1) enhance the affinity of the reactants towards the catalyst surface to improve proximity to ROS and therefore degradation probability; 2) enhance the amount of light absorbed by the catalyst which results in more electron-hole pair generation; 3) enhance the quantum yield by preventing charge recombination; or 4) improving the desorption of the products from the surface.

Many publications claim to have found a better catalyst because of the improvement of one or more of those aspects, while a complete description of the materials' properties is generally lacking. Especially for photocatalysts, many properties influence the overall activity, which makes a complete analysis of the relationship to the final photocatalytic activity challenging. Apart from experimental design parameters such as catalyst concentration in the slurry, irradiation area, light intensity, and pollutant concentration, the materials' properties are the key to improve the intrinsic photocatalytic activity. Accessible reaction surface area, light absorption/bandgap, extrinsic quantum yield (how many separated charge carriers are created from the incident light and that further react with the contaminant or generate ROS), and the affinity of the pollutants towards the surface play important roles and are related to the intrinsic material properties. In order to have insight into the difference in activity between various materials, all relevant properties should be taken into consideration and compared to enable the elaboration of the structure-activity relationships, which requires numerous characterization tools and analyses. For getting a complete picture of the prepared material, it is ubiquitous to address all these questions simultaneously.

The lack of insight often leads to discussions on what is the real reason for enhancement or suppression in photocatalytic performance for the degradation of dyes as a function of the surface modification. Pt decorated TiO₂ nanoparticles demonstrated in earlier studies, an improved activity for dye degradation¹⁰⁻¹². However, there exist still different theories why a low amount of platinum clusters onto TiO₂ (P25) enhances the photocatalytic activity. The explanations include enhanced charge separation¹³⁻¹⁶, improved light absorption¹⁷, and better O₂ adsorption¹⁸⁻²². On the other hand, especially for higher Pt loadings, the photocatalytic activity drops as proposed in earlier research due to charge recombination.^{18, 23-25} However, this explanation seems contradictory since a change from charge separation to charge recombination purely based on Pt loading does not seem likely. With their purely theoretical approach, Muhich et al. provided a reasonable explanation stating that Pt serves as a recombination center independent of the loading, where electrons and holes recombine in the Pt cluster. On the other hand, they advocate the importance of dissolved O₂ in solution, which adsorbs on the surface of Pt.¹⁸ The objective of this chapter is to substantiate Muhich's et al. theoretical approach by an experimental study elaborating on the different effects Pt clusters can have on the surface of TiO₂ (P25) focused on the charge carrier kinetics and to investigate the importance of dissolved oxygen.

2.1. EXPERIMENTAL SECTION

2.1.1. Materials

TiO₂ nanoparticles (P25, mean diameter ~21 nm, BET surface area of ~54 m²g⁻¹, information from supplier) were purchased from Evonik Industries (Hanau, Germany). Trimethyl(methylcyclopentadienyl)-platinum(IV) (MeCpPtMe₃) was obtained from Strem Chemicals and used as received. Acid Blue 9 (Brilliant Blue FCF) and Rhodamine B were purchased from Sigma Aldrich and were used without further purification.

2.1.2. Deposition

Prior to the deposition, the TiO₂ powder was sieved with a 250 μm mesh to break and exclude larger agglomerates. Platinum was deposited on TiO₂ (P25) using a homebuilt ALD setup in a fluidized bed under atmospheric pressure²⁶⁻²⁷. In brief, the powder was placed in a quartz glass column (diameter 26 mm, height 500 mm), which was then placed on a vertical vibration table (Paja 40/40-24) to assist fluidization. (MeCp)PtMe₃ was used as the Pt precursor, and oxygen gas was used as a counter reactant. For the ALD reactions, the Pt precursor was contained in a stainless-steel bubbler heated to 70 °C and the stainless steel lines, connecting both the Pt precursor and O₂ (Grade 5.0) individually to the reactor, were heated to 90 °C to avoid precursor condensation. The glass reactor was heated to 100 °C throughout the experiment using an infrared lamp, which was placed parallel to the column, with feedback control. For every experiment, 1.5 g of TiO₂(P25) powder was placed in the reactor column. Nitrogen (Grade 5.0), serving as a carrier gas for the precursor, was introduced through a distributor plate at the bottom of the column with a flow of 0.5 l/min resulting in a superficial gas velocity of 1.6 cm s⁻¹ to ensure proper fluidization and distribution of the precursor. The deposition process consisted of sequential exposures of the powders to the Pt precursor (20 sec – 5 min) and oxygen (5 min), separated by a purging step (5 min) using nitrogen as an inert gas.

After deposition, the powders were treated under an atmosphere of 5 % H₂ in nitrogen (v/v) in the fixed bed reactor with a flow of 100 ml/min. The temperature was ramped up from room temperature to 200 °C with a rate of 2 °C/min and then was held constant for 5 min after which the powder was allowed to cool down to room temperature.

2.1.3. Characterization

For the inductively coupled plasma - optical emission spectrometry (ICP-OES) analysis, approximately 30 mg of sample was digested in 4.5 ml 30 % HCl + 1.5 ml 65% HNO₃ + 0.2 ml 40 % HF acid mixture using a microwave. The digestion duration

in the microwave was 60 min. After the digestion, the samples were diluted to 50 ml with MQ water and analyzed with ICP-OES 5300DV. The samples were also diluted 20 times for Ti.

Transmission electron microscopy (TEM) pictures were acquired from a JEOL JEM1400 transmission electron microscope at 120 kV. As-deposited Pt:TiO₂(P25) nanoparticles were suspended in ethanol and transferred to Cu transmission electron microscopy grids (3.05 mm in diameter, Quantifoil).

X-ray photoelectron spectra (XPS) were recorded on a ThermoFisher K-Alpha system using Al K α radiation with a photon energy of 1486.7 eV. A sufficient amount of powders was immobilized on copper tape before loading into the XPS chamber. Scans were acquired using a 400 μ m spot size, 55 eV pass energy, and 0.1 eV/step with charge neutralization. The peaks positions were analyzed using the Thermo Avantage software after *SMART* type background subtraction and calibrating the measurements by taking the C 1s peak as a reference at 284.8 eV.

The Brunauer-Emmett-Teller (BET) surface area was measured on a Micromeritics Tristar II 3020. The samples were degassed overnight at 150 °C to remove adsorbed water on the surface.

Measurements of the mean agglomerate diameter (z-average) in dispersion and the zeta-potential have been carried out at a Beckmann-Coulter DelsaNanoC (Krefeld, Germany). Prior to the measurement, 15 mg of powder in 15 ml (MilliQ water) was dispersed by a sequence of 15 min stirring followed by sonication treatment for 20 s and an amplitude of 100 % (200 W) using a Bandelin Sonopuls HD 3100 sonicator (Berlin, Germany). Afterward, the dispersion was stirred for another 15 min. The mean particle size (z-average diameter) was measured using the cumulant analysis by averaging ten measurements with the detector configuration at an angle of 165° respective to the incident light beam. Three independent samples were measured for each material. The zeta-potential measurements were executed using the correlating flow cell of the same instrument using the same dispersion protocol. The pH of the dispersions was measured after 5 min of submerging the pH electrode (Votcraft pH-100ATC, Hirschau, Germany) into the freshly dispersed powder.

For adsorption measurements, the catalyst (2 g/l) was dispersed in a solution of Acid Blue 9 (16 mg/l_{aq}) or Rhodamine B (12 mg/l_{aq}) under vigorous stirring. After distinct time intervals, a liquid sample was analyzed using UV/Vis spectroscopy to measure the remaining concentration of the corresponding dye in solution.

UV/VIS-DRS measurements were performed using a PerkinElmer-Lambda 900 spectrometer equipped with an integrating sphere device scanning from 200 nm to 800 nm. The reflectance for various samples was measured where Barium sulfate served as a reference for 100 % reflection over the measured wavelength range.

The photoconductive behavior of the samples was measured with the time-resolved microwave conductivity technique (TRMC) on a custom-built setup described elsewhere.²⁸ The TRMC technique allows the measurement of the intrinsic photoconductivity of a sample without the need for external electrical contacts. A thin film sample was prepared on a quartz slide from a concentrated dispersion in ethanol by doctor blade coating and then dried at 80°C for 30 min and placed in a microwave cavity cell. The sample was continuously exposed to continuous X-band microwaves at an approximate resonance frequency of 8.5 GHz that were generated by a Gunn diode. Photoexcitation of the sample occurred with 3.5 ns full width half maximum laser pulses of tunable wavelength (240-2200 nm) using an *EKSPLA NT342B SH/SFG-10-AW Nd:YAG laser*. Upon photoexcitation, free and mobile charge carriers were generated, i.e. electrons and holes that absorb part of the incident microwave power expressed as: $\Delta P(t)/P$. The change in microwave power is proportional to a change in the photoconductance $\Delta G(t)$ as

$$\Delta P(t)/P = -K\Delta G(t).$$

Here K is a frequency-dependent sensitivity factor ($40 \cdot 10^3 \text{ S}^{-1}$) that follows from the resonance properties of the setup and the properties of the dielectric media present. The half-life of the transient photoconductance was used as a measure for charge transfer from TiO₂ to the Pt clusters on the hundred to microsecond timescale.

2.1.4. Photocatalytic testing

Photocatalytic testing under saturated Ar and O₂ atmosphere was done in a 30 ml custom made quartz reactor with 15 mg of powder and a 30 ml solution of Acid Blue 9 (16 mg/l) or Rhodamine B (12 mg/l). For better dispersion and degassing, the powder was put into the solution of Acid Blue 9 or Rhodamine B and sonicated in an ultrasonic bath (Ultrasonic Cleaner, USC–TH, VWR) for 10 min. For the experiments under an inert atmosphere, the solution was transferred into the reactor vessel in an N₂ glovebox to avoid exposure to the oxygen in the air. Afterward, the dispersion was stirred for 30 minutes under bubbling of Ar or O₂ gas in order to reach the desired atmosphere – inert vs. saturated solution of dissolved O₂. The samples were irradiated using a 500 W Deep UV Mercury lamp from Ushio (25.4 mW/cm²; see Appendix for light spectrum) and after distinct times samples of 0.5 ml were taken, filtered through a 0.45 μm PTFE filter and the filtrate was then analyzed using a UV/Vis spectrometer (Hach-Lange, DR5000, Düsseldorf, Germany) in a quartz glass cuvette with a thickness of 1 cm. A blank spectrum of water as the reaction medium was measured as a reference and automatically subtracted. The absorption was measured at 629 nm and 554 nm for Acid Blue 9 and Rhodamine B, respectively. According to quasi first-order kinetics, $\ln(C_0/C_t)$ was plotted vs. the time, and the slope of a linear regression represents the kinetic constant.

2.2. RESULTS AND DISCUSSION

2.2.1. Material synthesis and characterization

Changing the pulse times of the Pt precursor from 20 sec to 5 minutes, we could achieve loadings of Pt ranging from 0.04 wt% to about 0.7 wt% at a reaction temperature of 100 °C. We were able to precisely control the loading, which increases with pulse time (Fig. S2.1). Higher loadings (up to 3.13 wt % Pt) were achieved by applying up to four ALD cycles of Pt(Me₃)(MeCp) and O₂ at pulse times of five minutes each. After annealing in an H₂/N₂ atmosphere, the Pt clusters were converted to their more active metallic state²⁹, which has been confirmed by XPS with peaks arising at 71.28 eV (Pt5f_{7/2}) and 74.28 eV (Pt5f_{5/2}) (Fig. S2.2). TEM pictures confirmed the homogeneously distributed deposition of Pt clusters on the surface of TiO₂ with an average particle size of about 1.4 nm (Fig. 2.1).

Figure 2.1: a) TEM image of Pt clusters deposited on TiO₂ (P25) (0.34 wt % Pt), the bigger particles represent the TiO₂ particles, small black dots on the surface of TiO₂ indicate the Pt clusters, b) TEM image of Pt clusters deposited on TiO₂ (P25) (1.83. wt % Pt), insets: Particle size distribution of Pt clusters of corresponding samples.

2.2.2. Photocatalytic degradation of Acid Blue 9 and Rhodamine B

The photocatalytic activity was evaluated by decolorization of the two differently charged dyes, Acid Blue 9, which is solely negatively charged in natural conditions and Rhodamine B, a positively charged to zwitterionic molecule ($pK_a = 3.7$).³⁰ Both demonstrated a drastic increase in the photocatalytic activity for the loading of 0.34 wt % Pt as compared to TiO₂ (P25) for both Acid Blue 9 and Rhodamine B, followed by an activity drop to even lower values than the intrinsic value of TiO₂ (P25) for

higher Pt loadings (>1.8 wt % Pt) (Fig. 2.2, Fig. S2.3). The initial slight decrease in activity for very low loadings around 0.1 wt % Pt observed for both dyes is likely caused by the deposition process. Despite the annealing in a hydrogen atmosphere to convert the Pt into its metallic state, residues from the organic ligands might still be present at the surface of TiO₂ and have a negative effect on the photocatalytic activity.¹¹ This is very apparent, especially for the very low loaded samples, where the contamination may overpower the positive effect of the Pt deposition.

Figure 2.2: Kinetic constants for the degradation of a) Acid Blue 9 and b) Rhodamine B for various loadings of Pt on the surface of TiO₂ (P25).

Despite the well-established behavior of Pt on TiO₂ as a photocatalyst for dye degradation of showing an optimum³¹⁻³³, it still gives rise to the question what is the mechanism behind this initial increase and especially the subsequent drop to a lower activity as compared to pure TiO₂ (P25) for higher Pt loadings. It has been proposed in earlier studies that Pt on TiO₂ acts as an electron collector, making the lifetime of the separated electron and hole longer¹³ allowing those to react with the pollutant or water to create radicals enabling the degradation of the pollutants. This would explain the initial positive effect of the Pt but not why the activity drops to lower than TiO₂ (P25) for higher Pt loadings. Logically there must be at least two mechanisms behind – at least one positive and one negative – which gives this optimal loading behavior, as discussed in the introduction.

Since many parameters can affect the photocatalytic activity, Table 2.1 gives an indication which factors might be influential to the overall photocatalytic activity:

Table 2.1: Overview of the main (photo-)catalytic parameters as related to various material properties and factors influenced by them, and the corresponding analysis tools.

	Material Property	Affects	Analysis tool
General catalytic parameter	Surface area	Number of reaction sites	BET
	Accessible surface area in solution/agglomeration of catalyst particles	Diffusion/mass transfer	DLS
	Surface charge	Reactant adsorption	1) Zeta-potential 2) Amount of adsorbed dye on the surface
Photocatalytic parameter	Bandgap	Light absorption	UV/Vis-DRS
	Charge carrier kinetics	Lifetime charge carriers	TRMC
	Reactivity	Number of generated ROS (OH^* , O_2^{*-})	Catalytic testing under Ar and O_2 atmosphere

In the following, we will elaborate on each material property individually in order to check in a systematic way the role of Pt on TiO_2 (P25) as a photocatalyst:

1) Surface area

For heterogeneous photocatalysis, the available surface area is an important parameter to describe the activity of a catalyst. Since the reaction takes place in dispersion, it should be described both by the overall surface, which is measured by BET analysis, and the available surface for the reaction where surface coverage of materials or agglomeration of catalyst particles can be a reducing factor. BET analysis yields a surface area of $54.75 \text{ m}^2/\text{g}$ for Pt: TiO_2 (P25) (0.34 wt% Pt), equal to TiO_2 (P25) (from supplier, see Exp. Section), demonstrating that the deposited Pt clusters have only an insignificant effect on the BET surface area. However, since photocatalytic testing takes place in a dispersion of water, a change in the agglomerate size might influence the mass transfer of reactants to the inner surface of agglomerates and, therefore, the overall photocatalytic activity³⁴. Dynamic light scattering (DLS) showed a slight increase in the agglomerate size (z-average diameter) from $312 \pm 24 \text{ nm}$ (P25) to $408 \pm 64 \text{ nm}$ upon deposition of Pt clusters (0.34 wt% Pt) (Fig. 2.3a). The additional agglomeration is likely caused due to the deposition process where reactions of molecules on the surface might act as a “glue” between particles. However, the additional agglomeration is independent of the Pt loading and therefore acts more as a constant negative effect rather than as a dependency on the Pt loading. The reduced accessible surface due to stronger agglomeration might contribute to the small drop in

activity for very low loadings up to 0.1 wt % Pt.³⁴ Furthermore, Pt, itself acting as a co-catalyst on the surface of TiO₂ (P25), may reduce the active TiO₂ surface area for reactants. Taking into account the average Pt cluster size deposited on the TiO₂ surface of 1 – 2 nm, the surface coverage with Pt clusters only shows a limited decrease of less than 5 % of the TiO₂ surface, with increasing Pt cluster size, especially for low loadings (Fig. 2.3b). This indicates that the surface coverage of Pt on TiO₂ (P25) also should not be an influential factor on the photocatalytic activity.

Figure 2.3: a) Z-average diameter from DLS measurements of P25 and differently loaded Pt:TiO₂ (P25) catalysts, b) Calculated coverage of Pt on the TiO₂ (P25) surface as a function of the Pt cluster size for four different Pt loadings: 0.1 wt% (black), 0.5 wt% (red), 1 wt% (blue), 3 wt% (green).

2) Reactant adsorption

Dependent on the predominant reaction mechanism, the adsorption of the reactants plays an essential role in heterogeneous photocatalysis i.e. direct oxidation of the dye at the surface. The surface charge majorly influences the attraction or repulsion of differently charged molecules. The zeta potential often serves as an indication for the relative amount and the nature of charge present at the surface. Upon deposition of Pt, the zeta potential of the catalyst particles remains positive and at about + 30 mV (Fig. 2.4a) measured at a pH of 7.7 ± 0.3 . Positive charges are present at the surface of both TiO₂ (P25) and Pt:TiO₂(P25) due to the protonated –OH groups. Dye adsorption measurements (measured at a high powder concentration, see Exp. Section) of the negatively charged dye Acid Blue 9 and differently charged dye Rhodamine B are in agreement with the positive zeta potential. As expected, Acid Blue 9 strongly adsorbs on the surface of both TiO₂ (P25) and Pt:TiO₂(P25), whereas Rhodamine B shows limited adsorption due to only weak interaction with the TiO₂ surface (Fig. 2.4b). The Acid Blue 9 adsorption decreases for higher Pt loadings, while Rhodamine B adsorbs accordingly slightly better to the surface indicating that the zeta potential slightly decreases for higher Pt loadings. Despite the opposite adsorption behavior of

Rhodamine B and Acid Blue 9, the photocatalytic activity to degrade Acid Blue 9 and Rhodamine B shows similar optimal behavior as a function of the Pt loading. This demonstrates that differences in dye adsorption have no impact on the general photocatalytic behavior of Pt:TiO₂(P25) vs. pure TiO₂ (P25).

Figure 2.4: a) Zeta-potential of various Pt loaded TiO₂ (P25) samples; b) Dye adsorption studies with a catalyst concentration of 2 g/l. Red bars indicate the amount of adsorbed Rhodamine B on the surface of various loaded Pt:TiO₂(P25), blue bars indicate the adsorption of Acid Blue 9 on the surface of Pt:TiO₂(P25). Samples were taken after 30 min of stirring in the dark.

Summarizing the external effects of surface area and pollutant adsorption of Pt:TiO₂ (P25) compared to TiO₂ (P25), we can conclude that both properties play if at all only a minor role on the dependence of the photocatalytic activity on Pt loading. Both the surface area measured by BET and the calculated actual free TiO₂ surface area from the surface coverage of Pt clusters only show a minor decrease. The agglomerate size instead generally increases for the Pt:TiO₂(P25) which is due to the deposition process rather than related to the loading. Furthermore, the adsorption studies of different pollutants demonstrated the independence of the general photocatalytic behavior on the pollutant adsorption since for both cases of high and low reactant adsorption – dependent on the charge of the dye – Pt:TiO₂(P25) shows the same trend in photocatalytic activity as a function of the Pt loading.

After discussing the influence of the external parameters, we now will look more into the *photo*-catalytic parameters, i.e. light absorption, charge carrier kinetics, and reactivity.

3) Light absorption and charge carrier dynamics

A common approach in photocatalyst development is to reduce the bandgap of the material in order to increase the photon absorption of the solar spectrum. This approach usually requires the incorporation of heteroatoms into the crystal lattice of the base material. In contrast, our deposition of Pt clusters on the TiO₂ surface is not expected to change the bandgap of TiO₂. However, Pt clusters may absorb light of all

wavelengths as a result of the metallic character. The UV/VIS-DRS spectra show increased absorption in the visible at higher Pt loadings (Fig. 2.5a), which is caused by metallic Pt clusters.^{12, 35} On the other hand, the presence of Pt clusters do not change the absorption edge which indicates the bandgap of TiO₂ remains unaffected disregarding possible band bending near a junction to Pt. This is also expected because Pt(0) clusters are deposited on the surface and Pt is not incorporated in the TiO₂ lattice. Additionally, it indicates that possible other valencies (i.e. Pt(II) and Pt(IV) of Pt) were reduced to Pt(0) by H₂ post-treatment and are not affecting the band structure of TiO₂.

Figure 2.5: a) Absorption spectrum UV/Vis DRS spectra for different loaded Pt:TiO₂(P25), b) Half time ($\tau_{1/2}$) of the mobile charge carriers measured by TRMC, Inset: Transient decay of the mobile charge carrier.

Light absorption by the TiO₂ leads to the creation of mobile electrons and holes. The mobile electrons may transfer into the Pt clusters that allow redox reactions to occur. The electrons that transfer into the Pt clusters become immobile. With the microwave conductivity technique, the decrease in TiO₂ photoconductance is probed owing to the loss of free and mobile electrons in the TiO₂ resulting from charge transfer to the Pt. As the electrons in small noble metal clusters are immobile, no photoconductivity can come from these transferred electrons.³⁶ As such, the kinetics of the photoconductance transients provide a value for the charge transfer to Pt on the nanosecond to microsecond timescale. The half-life ($\tau_{1/2}$) of the free electrons in the TiO₂ decreases with increasing Pt loadings (Fig. 2.5b), which clearly indicates that the charge carrier dynamics are affected by the presence of Pt at the TiO₂ nanocrystal surface. Even at very low Pt loadings of 0.04 wt.%, the effect is very pronounced. This shows that electron transfer from TiO₂ to Pt is energetically favorable and therefore supports charge separation. The transferred electrons in the Pt clusters may support different reactions determining the fate of the electrons. Pt is not only well known as an H₂ evolution catalyst by reducing H⁺ with the collected electrons³⁷⁻³⁸ but is also shown to

readily adsorb O_2 on its surface^{18, 20}. The reduction of adsorbed O_2 to $O_2^{\cdot-}$ superoxide radical by the collected electrons would positively influence the photocatalytic activity for pollutant degradation, improving the generation of ROS.⁹ Therefore, photocatalytic degradation experiments using different environments, such as dispersions saturated with O_2 and Ar atmosphere, would give insight into the influence of adsorbed O_2 on the photocatalytic activity of Pt:TiO₂(P25). Excluding O_2 from the reaction medium will block the generation of superoxide $O_2^{\cdot-}$ radicals via the consumption of the conduction band electrons. The photocatalytic activities for various Pt loadings under saturated O_2 and Ar atmosphere are displayed in Figure 2.6:

Figure 2.6: Degradation of different dyes in Ar and Oxygen atmosphere: a) Time dependent absorption of dissolved Acid Blue 9 in solutions of TiO₂ (P25) with various Pt catalyst loadings in an O₂ atmosphere and b) in an Ar atmosphere. c) Kinetic constants for the conversion of Acid Blue 9 at different Pt catalyst loadings in an O₂ (blue, 0 – 5 min, more information see SI Fig. S2.4) and Ar atmosphere (green, 10 – 20 min, more information see SI Fig. S2.4). d) Time dependent absorption of dissolved Rhodamine B in dispersions of TiO₂ (P25) with various Pt catalyst loadings in an O₂ and e) Ar atmosphere. f) Kinetic constants for the conversion of Rhodamine B at different Pt catalyst loadings under O₂ atmosphere (red) and Ar atmosphere (black).

Interestingly, we can observe 4 different effects (indicated by the numbers in Fig. 2.6c) and f)):

- 1) Under O₂ atmosphere, the photocatalytic activity increases to the maximum at 0.34 wt% Pt for both dyes (see also Fig. 2.2).
- 2) Further increase in the loading of Pt decreases the photocatalytic activity to even lower values than TiO₂ (P25) for both dyes (see also Fig. 2.2).
- 3) Photoactivity only halves for TiO₂ (P25) in Ar atmosphere for Acid Blue 9 but significantly diminishes for the degradation of Rhodamine B.
- 4) For both dyes, the photocatalytic activity drops drastically in Ar atmosphere for all Pt:TiO₂(P25)samples.

The degradation of Rhodamine B in inert atmosphere results in a strong suppression of the photocatalytic activity for both TiO₂ (P25) and Pt:TiO₂(P25) (Fig. 2.6f). For Acid Blue 9, the behavior is different. While the argon atmosphere hampers the activity of Pt:TiO₂(P25)drastically, especially in the later stage of the reaction, a significantly higher activity remains for TiO₂(P25) compared to Pt:TiO₂(P25) (Fig. 2.5a-c). These results show that dissolved O₂ is a crucial factor in the degradation of both dyes. Without O₂ dissolved in the water, Pt:TiO₂ (P25) is a worse catalyst than pure TiO₂ (P25) for the degradation of Acid Blue 9. Since the electron transfer within materials is usually not influenced by conditions in the solution, the photo-generated electrons will transfer in both cases (O₂ and Ar atmosphere) to the Pt clusters raising the question about the fate of the electrons in the Pt clusters. Two options can be proposed: 1) the electrons are harvested from the surface of the Pt cluster to generate ROS, 2) in case no electron harvesting at the surface is possible, additional photo-generated electrons will charge up the Pt cluster, increasing the probability of charge recombination at the Pt-TiO₂ interface.

In an oxygen atmosphere, the dissolved O₂ will adsorb on the surface of Pt and subsequently consume the electrons available in the Pt cluster to generate superoxide (O₂^{-•}) radicals, which will degrade the dyes in the water. In the case of an Ar atmosphere, the electrons cannot react with O₂ and, therefore, won't be able to assist this photocatalytic degradation route. Nevertheless, that would still allow the holes in the TiO₂ to react on the surface to generate OH radicals or degrade the dye directly. However, the activity drops drastically for Pt:TiO₂(P25) which demonstrates that not only neither of the degradation pathways (via direct oxidation, via hydroxyl or superoxide radical formation) but also other sacrificial reactions such as H₂ evolution (which could harvest the electrons form the Pt clusters and allow degradation pathway via the valence band) are not very active under these conditions of argon atmosphere. This behavior suggests to be caused by the intrinsic behavior of Pt. Theoretical calculations from Muhich et al. ¹⁸ indicate that Pt (in addition to an electron collector) also acts as an electron-hole recombination center, where electrons and holes recombine in the Pt cluster, and this affects the activity more predominantly when the electrons cannot be harvested by O₂ leading to a worse photocatalytic activity compared to TiO₂. On the other hand, according to Muhich's calculations, Pt clusters

on the surface of TiO_2 will improve the adsorption of O_2 with respect to the intrinsic TiO_2 surface, improving the ROS formation to degrade organic pollutants faster.¹⁸ From our results, it becomes clear that for low Pt loadings, O_2 can easily consume all the electrons from the few Pt clusters because the surface of Pt is supplied with enough O_2 so that the benefit of electron consumption by adsorbed O_2 is stronger than the recombination of electrons with holes. As soon there is too much Pt on the surface, insufficient O_2 can be provided for the consumption of all electrons provided by the Pt-surface due to diffusion limiting the transport of O_2 to the Pt-surface, which leads to a more pronounced electron-hole recombination at the Pt- TiO_2 interface becoming the rate-limiting step in the reaction mechanism. This interaction between a beneficial (O_2 adsorption and electron consumption) effect and a disadvantageous (electron-hole recombination) effect explains why an optimal Pt loading for the photocatalytic degradation of dyes by TiO_2 -Pt is observed. In this context, it is expected that not only the Pt loading but also the Pt cluster size and morphology will play an essential role³⁹⁻⁴⁰ in the O_2 adsorption versus charge recombination mechanism due to the difference in surface to volume ratio, which would be a relevant property to investigate in future research.

The degradation of Rhodamine B under an argon atmosphere is majorly obstructed for both TiO_2 (P25) and Pt: TiO_2 (P25) (Fig. 2.6d-f). The difference to Acid Blue 9 is the charge and the related adsorption on the surface. The zwitterionic Rhodamine B molecule does not adsorb on the surface due to only weak electrostatic interactions (Fig 2.4b). This means that a direct degradation of dyes via holes in the TiO_2 valence band is unlikely. Similarly, dye degradation via surface generated OH^* has no substantial contribution. Without both, this degradation mechanism and the dominance of the consumption of the conduction band electrons by O_2 , the photocatalytic activity drops to a minimum as a result of the charge recombination. In contrast, TiO_2 (P25) readily degrades Acid Blue 9 in an Ar atmosphere. This is caused by the degradation reaction of free holes in the TiO_2 with absorbed Acid Blue 9. However, the fate of excited electrons in the CB remains unclear from our present experiments. One possibility is that electrons may be harvested by either other sacrificial reactions such as reduction of water or the adsorbed dye molecules, but this investigation is beyond the scope of this study. This finding substantiates that direct oxidation has a high significance in the degradation pathway of Acid Blue 9 using TiO_2 (P25).

In the case of the Pt: TiO_2 (P25) samples, the activity changes for Acid Blue 9 degradation in Ar atmosphere throughout the experiment from an initial higher value (0 – 10 min), which about 50 % lower than that of TiO_2 (P25), to a very low activity after 10 min (Figs. S2.3, S4.4). Despite that difference in activity according to 1st order kinetics, applying those kinetics gives a chance to still compare both cases. The higher activity in the beginning (0 – 10 min), indicating a deviation from pure quasi 1st order kinetics during the whole course of the reaction, could have two reasons. Since Acid Blue 9 adsorbs on the surface the degradation on Pt: TiO_2 (P25) occurs via the generated holes from the TiO_2 . The electrons will transfer to the Pt clusters, where the harvesting of electrons due to a lack of O_2 is not possible, which leads to a charge up

of the Pt increasing the recombination rate with the holes in the TiO₂. Secondly, Pt is often used as an oxygen reduction catalyst³⁹ and readily adsorbs oxygen at its surface. Even with extensive degassing via sonication while purging with Ar and a continuous Ar flow prior to the reaction, the Pt nanoclusters might be able due to strong interaction with O₂ to bind oxygen at its surface. This limited amount of oxygen, bound on the Pt surface, is consumed in the first stages of the irradiation to harvest the electrons in the Pt, leading to decomposition of the adsorbed Acid Blue 9 with a high reaction rate. After depletion of the remained dissolved and adsorbed O₂, the kinetic constant further drops due to the increasing probability of charge recombination of the electrons in the Pt clusters with the holes in the TiO₂. However, this behavior of an initial higher kinetic constant is not observed for the degradation of Rhodamine B in Ar atmosphere, drawing the importance towards the adsorption of the pollutant. Therefore, it is more likely that the direct oxidation due to adsorption of Acid Blue 9 is the determining factor for this behavior.

Figure 2.7: Proposed mechanism of photocatalytic dye decomposition for Pt:TiO₂(P25) in O₂ (left) and Ar (right) atmosphere, the thickness of the arrows indicates the probability of the events.

Summarizing the photocatalytic properties, Pt clusters on TiO₂ (P25) nanoparticles don't affect the creation of charge carriers by light absorption in TiO₂, observing only an absorption increase in the range of visible light caused by the metallic state of Pt itself but no change in the UV-absorption properties of TiO₂. However, with higher loading, the Pt clusters themselves will absorb and consequently block light reaching the TiO₂ surface with a possible negative influence on the photocatalytic activity. The fate of charge carriers is strongly determined by the deposition of Pt clusters. Photogenerated electrons are separated from the holes by transferring to the Pt clusters and will react further in the presence of O₂ to generate reactive oxygen species. On the other hand, in case no O₂ is present, electrons will not be consumed by sacrificial redox reactions, but easily recombine with the holes in TiO₂ inhibiting the photocatalytic activity (Fig. 2.7). This makes the presence of sufficient O₂ the crucial factor determining the efficiency of the photocatalytic degradation of dyes using Pt:TiO₂(P25) because dissolved O₂ will harvest the separated electrons in the Pt cluster, preventing the electron-hole recombination independent on the pollutant.

This detailed insight into the photocatalytic dye-degradation mechanism using Pt:TiO₂(P25) gives the opportunity to smartly design photocatalytic materials that optimize different parts of the photocatalysis mechanism, such as the improvement of light absorption or the efficient generation of ROS via electrons in the conduction band. Furthermore, understanding the behavior in different atmospheres is especially valuable for later developments of bringing the Pt:TiO₂(P25) photocatalyst into practice where contaminated water sources might suffer a lack of oxygen due to external influences such as algae growth.

2.3. CONCLUSIONS

Using an atomic layer deposition, we deposited Pt clusters on TiO₂ (P25) nanoparticles at a temperature as low as 100 °C. Depositing various loadings of Pt (0.04 wt % to 3.13 wt % Pt) gave us the opportunity to investigate the role of Pt on TiO₂ (P25) for a range of Pt loadings on the photocatalytic degradation of Acid Blue 9 and Rhodamine B. The synthesized Pt:P25 catalysts exhibited an optimal photocatalytic activity at very low loadings (i.e. 0.36 wt. % Pt) for the degradation of Acid Blue 9 and Rhodamine B under ambient conditions. However, experiments under Ar versus O₂ atmosphere demonstrated the importance of O₂ dissolved in the reactor suspension. Testing the degradation of two different pollutants under inert conditions (Ar atmosphere) the Pt:TiO₂(P25) catalyst showed a tremendous decrease in activity compared to the reaction under O₂ atmosphere, independent on the Pt loading, whereas TiO₂ (P25) remained partly active for the degradation of Acid Blue 9. It can be concluded that O₂ is the critical factor to efficiently harvest the at the TiO₂-Pt interface separated electrons, which are transferred to the Pt clusters. Without the consumption of electrons by O₂ at the Pt surface, the recombination of electrons in the Pt and holes at the Pt-TiO₂ interface dominates the reaction mechanism leading to a poor photocatalytic activity. In an O₂ atmosphere, for low loadings of Pt, the consumption of electrons by oxygen adsorbed on the Pt surface plays the predominant role in enhancing the photocatalytic activity. At higher Pt loadings, the disadvantageous charge recombination properties of Pt exceed the positive effects of O₂ adsorption and the overall photocatalytic efficiency drops even below the initial value of TiO₂ (P25). These findings add experimental proof to the theoretically proposed reaction mechanism by Muhich et al.¹⁸

For the calculation of the kinetic constants, values originated from a too low concentration were excluded. Due to the dependency on the natural logarithm, the error would increase, leading to unreliable results. Furthermore, at the end of the reaction, 1st order kinetics are not valid anymore due to a lack of reactant.

Figure S2.4: Kinetic constants for the degradation of Acid Blue 9 in Ar atmosphere (Fig. S3b). The calculation of the kinetic constant is divided into two reaction regimes. Blue circles represent the kinetic constant calculated using the values from 0 – 10 min. Green squares represent the kinetic constant using the values 10 – 20 min. For P25, no change in kinetics could be observed. Therefore, the kinetic constant was calculated using all values from 0 – 20 min.

Figure S2.5: Irradiance spectrum (black) from Deep UV Mercury lamp used to irradiate photocatalysts. Since the sample was irradiated from the side, this spectrum represents the light which reached inside the reactor. As insets are the absorption spectra from Acid Blue 9 (blue) and Rhodamine B (red) depicted in the range of 450 to 700 nm.

Atmospheric pressure atomic layer deposition of ultralow-loading Cu₂O nanoclusters on TiO₂ nanoparticles for enhanced photocatalytic removal of organic pollutants

This work presents a gas-phase approach for the synthesis of Cu₂O/TiO₂ powder-based photocatalysts using atomic layer deposition (ALD). The process was carried out in a fluidized bed reactor working at atmospheric pressure using (trimethylvinylsilyl)-hexafluoroacetylacetonate copper(I) as Cu-precursor and water vapor as oxidizer. With this technique, ultras-small Cu₂O clusters with an average diameter of 1.3 – 1.5 nm and narrow particle size distribution were successfully deposited onto P25 TiO₂ nanopowder. The self-saturating chemical reactions between the Cu-precursor and H₂O vapor and the linear growth of ALD were achieved, allowing us to control the loading of Cu₂O on the TiO₂ surface. The photocatalytic performance of Cu₂O/TiO₂ photocatalysts was tested by the degradation of organic dyes, including Rhodamine B (RhB), methyl orange (MO) and methylene blue (MB). We found that with a Cu loading of 0.4 at.%, Cu₂O/TiO₂ exhibited excellent photocatalytic activity, which was 120 %, 150 %, and 70 % higher than the photocatalytic activity of P25 TiO₂ in the degradation of RhB, MO, and MB, respectively. The photocatalytic reaction mechanism was further investigated for the degradation of RhB, revealing the dominating role of holes, which contributed to both direct surface oxidation and indirect oxidation (i.e., via the formation of hydroxyl radicals). The results obtained from our work provide a fast, feasible, and scalable process to deposit ultras-small Cu₂O clusters in a highly controlled fashion for engineering the surface of TiO₂ powder-based materials.

3.1. INTRODUCTION

Owing to its excellent photocatalytic activity, high chemical stability, low cost, and nontoxicity, titanium dioxide (TiO₂) is the most popular photocatalyst that has been used in many environmental and energy applications, such as air purification, water treatment, hydrogen production, and photovoltaics.¹⁻⁷ Among various TiO₂ nanomaterials, the commercial Evonik P25 TiO₂ nanopowder commonly exhibits the highest photocatalytic efficiency.⁸ The key factor that enables the superior catalytic performance of P25 is the charge transfer at the interfaces between the interconnected rutile and anatase particles⁸⁻⁹, which are the main components of P25 TiO₂. Accordingly, P25 TiO₂ is composed of nanosized anatase (ca. 70 – 85 %) and rutile crystallites and a small fraction of amorphous TiO₂.⁹⁻¹¹ Due to the different band alignments between anatase and rutile, the interconnection between the anatase and the rutile nanoparticles facilitates the electron transfer from anatase to rutile¹², which enhances the charge separation and consequently improves the photocatalytic efficiency.^{8-9, 12-14} Nevertheless, despite its superior catalytic activity, the rapid recombination of photogenerated charge is still a major issue of P25 TiO₂ photocatalyst.^{10, 15-17}

Various strategies have been developed for reducing the charge recombination in TiO₂, such as surface treatment and doping,^{11, 18-22} hydrothermal treatment for improving the interconnection of TiO₂ nanoparticles and crystallization of the amorphous portion,^{8, 13, 23} and surface engineering by coupling with a metallic or semiconducting material.²⁴⁻³³ In the last case, noble metals, such as Pt, Pd, Au, and Ag have commonly been the materials of choice.^{25-27, 30-32, 34-37} On the one hand, by virtue of their excellent catalytic activities, noble metals can act as co-catalysts when coupling with TiO₂, resulting in a synergic effect that enhances of photocatalytic performance.^{31, 36-37} On the other hand, as the Fermi levels of noble metals are commonly lower than the conduction band of TiO₂, noble metals can act as electron sinks that facilitate the electron transfer from TiO₂. This increases the charge separation, which further improves the photocatalytic efficiency.³⁸⁻³⁹ However, the high cost is a limiting factor that hinders their practical applications. Therefore, semiconducting metal oxides (SMOs), such as CuO, Fe₂O₃, and WO₃, which have been demonstrated as excellent alternative engineering materials for reducing charge recombination in TiO₂, are nowadays more attractive.^{28-29, 33, 40-41} The coupling of an SMO and TiO₂ promotes the photogenerated charge transfers at the interface, which is governed by the band alignment between TiO₂ and the SMO. For instance, in CuO/TiO₂ photocatalysts, as the conduction band of CuO is lower than that of TiO₂, under UV irradiation, electrons are driven to migrate from TiO₂ to CuO, thereby increasing the lifetime of holes in TiO₂.²⁹ This mechanism was also applied for the charge transfer in Fe₂O₃/TiO₂ photocatalysts.²⁸ However, in a WO₃/TiO₂ photocatalyst, as both the conduction band and the valence band of WO₃ are lower than those of TiO₂, respectively, a double-charge transfer can take place, in which electrons migrate from TiO₂ to WO₃ while holes migrate in the opposite

direction.⁴² The charge transfers between the two semiconductors result in photocatalytic enhancement.

Cuprous oxide (Cu_2O) is among the metal oxides that have been used to improve the photocatalytic performance of TiO_2 .⁴³⁻⁴⁵ It is a p-type semiconductor whose conduction band is much higher than that of TiO_2 and many other semiconductors.⁴⁶ As a consequence, the coupling of Cu_2O and TiO_2 can generate a type-II heterostructure, which allows different charge transfer mechanisms between the two materials.⁴⁶⁻⁴⁷ In particular, two main charge transfer mechanisms have been observed in $\text{Cu}_2\text{O}/\text{TiO}_2$ photocatalysts. The first mechanism is related to the double-charge transfer between the two semiconductors.⁴⁶ According to this mechanism, as Cu_2O is a p-type semiconductor, while TiO_2 is an n-type semiconductor, the coupling of Cu_2O and TiO_2 results in the formation of a p–n junction that creates a built-in electric field. This electric field promotes the electron transfer from Cu_2O to TiO_2 due to the higher conduction band of Cu_2O (i.e., more negative) with respect to that of TiO_2 , while holes are driven to migrate in the opposite direction.^{17, 43, 48} The other mechanism is related to the recombination between electrons in the conduction band of TiO_2 and holes in the valence band of Cu_2O ^{46, 49}, which is commonly known as the Z-scheme mechanism.⁵⁰⁻⁵¹ Both mechanisms reduce the charge recombination in bulk TiO_2 , which consequently improves the photocatalytic performance. Importantly, the Z-scheme charge transfer between Cu_2O and TiO_2 can protect the Cu_2O from photocorrosion.^{46, 52} Therefore, $\text{Cu}_2\text{O}/\text{TiO}_2$ photocatalysts have attracted great attention for applications in energy conversion and photocatalysis.^{17, 43, 45, 48, 53-56}

Up to date, $\text{Cu}_2\text{O}/\text{TiO}_2$ photocatalysts have been mostly synthesized by wet-chemistry methods, such as precipitation,^{43, 55} sol-gel,⁵⁶ chemical batch deposition,⁵⁷ solvothermal,⁵⁸ impregnation,⁵⁹ solvent reduction,^{54, 60} and electrochemical.⁶¹ Despite their great advantages of simplicity, low-cost, and the ability to develop various nanostructures, wet-chemistry methods inherently contain several drawbacks. On the one hand, the use of large amounts of chemicals and solvents for the synthesis is not favorable for large-scale production due to environmental issues. On the other hand, wet-chemistry is usually time-consuming due to the requirements of post-processing and treatment of the products, such as washing, drying, and annealing, which can take from several hours to tens of hours.^{46, 54, 58-60} Moreover, wet-chemistry methods may encounter difficulties in controlling the loading, size, and composition of the deposited materials due to their strong dependence on experimental conditions, such as precursor concentration, reaction time and temperature, concentration and types of solvents, etc.⁶² Therefore, developing a synthesis process that can tackle the disadvantages of wet-chemistry methods is essentially needed. To this end, atomic layer deposition (ALD) has emerged as an excellent candidate, which has been applied for depositing a number of materials such as Ni, Co, Pt, Pd, Al_2O_3 , and SiO_2 on powder- and particle-based substrates.^{26-27, 63-68} This is a solvent-free, gas-phase deposition technique, in which the substrate is exposed to the precursors sequentially and separately. As a consequence, the chemical reactions only take place on the substrate surface, and importantly, reactions are self-limiting, which are independent of

precursor concentration, reaction time, and temperature.⁶⁹⁻⁷⁰ Therefore, ALD allows controlling the amount of deposited materials at the atomic level.⁷¹

Here, we present an ALD approach for the first time to synthesize multigram-scale Cu₂O/TiO₂ powder-based photocatalysts in a fast, solution-free, and controllable manner. The process was carried out in a fluidized bed reactor (FBR) operating at atmospheric pressure using (trimethylvinylsilyl)-hexafluoroacetylacetonate copper(I) (Cu(I)(hfac) (TMVS)) as the precursor and water vapor as the oxidizer. This enabled the growth of ultrasmall Cu₂O clusters with diameters in the range 1.3 – 1.5 nm, and a narrow particle size distribution on TiO₂ nanoparticles. We demonstrate that the self-limiting characteristics and linear growth of Cu₂O ALD were achieved, which allowed us to tailor the loading of Cu₂O in a controllable fashion. The photocatalytic activity of Cu₂O/TiO₂ photocatalysts was investigated by the photodegradation of organic dyes, including Rhodamine B (RhB), methyl orange (MO) and methylene blue (MB). We found that with a Cu loading of 0.4 %, the photocatalytic activity of Cu₂O/TiO₂ was significantly enhanced, which was 120 %, 150 %, and 70 % higher than that of pristine TiO₂ in the degradation of RhB, MO and MB, respectively. The photocatalytic reaction mechanism was further investigated for the degradation of RhB, revealing the dominating role of holes, which contributed to both direct surface oxidation and indirect oxidation (i.e., via the formation of hydroxyl radicals). Our approach provides a rapid, feasible, and scalable process to deposit ultrasmall Cu₂O clusters in a highly controlled fashion for engineering the surface of TiO₂ powder-based materials.

3.2. EXPERIMENTAL SECTION

P25 TiO₂ powder (mean diameter of 21 nm and specific surface area of 54 m²g⁻¹) was purchased from Evonik Industries (Hanau, Germany). Cu(I)(hfac)(TMVS) contained in a stainless steel bubbler was purchased from ADVANCED TECH. & IND. CO., LTD. Rhodamine B (RhB), methanol, potassium chlorate (KClO₃), dimethyl sulfoxide (DMSO), and ethylenediaminetetraacetic acid (EDTA) were acquired from Sigma Aldrich and used without further purification.

The deposition was carried out in a fluidized bed reactor operating at atmospheric pressure, as described elsewhere.⁷² In brief, the reactor consisted of a quartz glass column (diameter of 26 mm and height of 500 mm) placed on a vertical vibration table (Paja 40/40-24) to assist the fluidization of the nanoparticles. The reactor was heated by an IR lamp; the temperature inside the reactor was measured by a type-K thermocouple, which was connected to a PID controller to maintain the reactor temperature at a constant value.

Cu₂O was deposited using Cu(I)(hfac)(TMVS) as the precursor and H₂O as the oxidizer. The Cu-precursor bubbler was maintained at 60 °C, whereas the H₂O bubbler was kept at room temperature. The deposition temperature was 250 °C. During the deposition, a temperature variation of ±10 °C was observed. Pressurized nitrogen

(99.999 vol.%) was used as the carrier gas. For a typical ALD process with 1.3 g TiO₂ powder, a N₂ flow of 0.50 L min⁻¹ was introduced from the bottom of the glass column to fluidize the powder, which was supported by a microporous distributor. For the study on the self-limiting characteristics of Cu₂O ALD, the exposure time for Cu(I)(hfac)(TMVS) was varied from 2.5 min to 30 min, whereas the exposure time for H₂O was varied from 2.5 min to 10 min. A purge of N₂ for 5 min was introduced in between the precursor doses to remove the reaction by-products and the residual precursors.

The crystal structure of the Cu₂O/TiO₂ powder was studied by X-ray diffraction (XRD) technique. XRD patterns were obtained by a PANalytical X-pert Pro diffractometer with Cu K α radiation, secondary flat crystal monochromator, and X'celerator RTMS Detector system. The Cu concentration of the deposited Cu₂O was determined by ICP-OES technique. For each measurement, approximately 30 mg of sample was destructed in a solution consisting of 4.5 ml 30 % HCl, 1.5 ml 65 % HNO₃ and 0.2 ml 40 % HF using a microwave. The destruction time in the microwave was 60 min. After the destruction, the samples were diluted to 50 ml with MQ and analyzed with ICP-OES 5300DV.

TEM micrographs of the samples were acquired using a JEOL JEM1400 transmission electron microscope operating at a voltage of 120 kV and a current density of 50 pA cm⁻². As-deposited Cu₂O/TiO₂ nanoparticles were suspended in ethanol and transferred to Quantifoil TEM grids (Cu, 3.05 mm in diameter).

X-ray photoelectron spectra (XPS) were recorded on a ThermoFisher K-Alpha system using Al K α radiation with a photon energy of 1486.7 eV. The powder samples were immobilized on Carbon tape before loading into the XPS chamber. Scans were acquired using a 400 μ m spot size, 55 eV pass energy, and 0.1 eV/step with charge neutralization. The peaks positions were analyzed by calibrating the C 1s peak at 284.8 eV. The background was subtracted using ThermoAvantage software, applying a "smart" type background subtraction.

The photocatalytic activity of the Cu₂O/TiO₂ catalysts was investigated via the degradation of RhB solution under UV-light irradiation. For each test, 10 mg of the catalyst was dispersed in 80 ml aqueous RhB solution (10 mg L⁻¹) contained in a 200-ml glass beaker (diameter of 8 cm). To reach the adsorption-desorption equilibrium, the solution was stirred in the dark for 30 min. Thereafter, the suspension was exposed to UV-radiation generated by a mercury lamp (25 W, 620 lux at the surface of the reactor) for different exposure times. The suspension was then centrifuged to separate the solid catalyst from the solution. Finally, the solution was analyzed by UV-visible spectroscopy using a Jenway's 6800 double beam spectrophotometer to determine the residual concentration of the RhB in solution. The catalytic activity was analyzed by the first-order kinetics where the slope of $\ln(c_t/c_0)$ vs time gives the kinetic constant. For studying the role of charge carrier in the photodegradation of RhB, KClO₃, DMSO, and EDTA were used as the electron, hole,

and hydroxyl radical scavenger, respectively, which was added to the solid-dye suspension prior to the UV-irradiation.

3.3. RESULTS AND DISCUSSION

3.3.1. Surface morphology, composition, and structure

ALD of Cu₂O using Cu(I)(hfac)(TMVS) and H₂O was previously reported by Muñoz-Rojas et al.,⁷³ demonstrating that the process carried out at atmospheric pressure enabled the deposition of stoichiometric Cu₂O thin films on glass substrates at temperatures from 150 to 300 °C. Although the initial stage of the growth was not studied, the granular surface of the films observed by SEM suggests that the growth of Cu₂O starts with the formation of 3D islands. Here, our ALD in an FBR at 250 °C enabled the growth of ultrasmall clusters on the surface of TiO₂ nanoparticles. Fig. 3.1a shows the TEM image of the Cu₂O/TiO₂ nanoparticles with a Cu atomic concentration of 0.4 %. The Cu₂O particle size distribution (PSD) is shown in the inset of the TEM image. A narrow PSD with an average diameter of 1.3 ± 0.4 nm was obtained, which increased to 1.5 ± 0.4 nm for the Cu₂O/TiO₂ with a Cu atomic concentration of 1.7 % (Fig. 3.1b). XPS analysis confirms the Cu₂O phase, which is indicated by the two peaks at a binding energy of 932.6 and 952.6 eV (Fig. 3.1c). These two peaks represent the doublet states Cu2p_{3/2} and Cu2p_{1/2} of Cu2p core level of Cu₂O. The symmetric shape of the peaks and the absence of the satellite peaks at approximately 943 eV suggests the absence of CuO phase.

Moreover, compared to the XRD pattern of pristine TiO₂, the XRD patterns of Cu₂O/TiO₂ exhibit additional peaks at 36.0° and 43.2°, which are ascribed to the (111) and (200) planes of cubic Cu₂O phase, respectively, whereas no diffraction peak of CuO phase was found. We note that the positions of Cu₂O diffraction peaks exhibited a slight shift with respect to the standard peak positions of Cu₂O (JCPDS 05–0667). This is due to the effect of particle size on the XRD pattern, which is observed for particles with sizes below 5 nm.⁷⁴ According to the recent research by Vorontsov et al., this effect is caused by the interference fringes and is not taken into account when considering XRD patterns in standard software. As a consequence, significant shifts up to a few degrees in the XRD patterns can be observed. Nevertheless, this does not rule out the contribution of the distortions and microstrain of the crystalline structure.

Figure 3.1: TEM images of Cu₂O ultrasmall clusters with the average diameter in the range of 1.3 – 1.5 nm (the smaller and darker dots) on TiO₂ nanoparticles with Cu concentration of 0.4 % (a) and 1.7 % (b), and the corresponding XPS spectra of Cu 2p core-level (c). Their XRD patterns are shown in (d), which includes the XRD pattern of P25 TiO₂ as the reference.

The self-limiting characteristics of Cu₂O ALD were investigated by varying the dose time of the precursors. We note that, in a conventional ALD process, the dose time usually ranges from milliseconds to seconds since the materials are commonly deposited on flat substrates, i.e., with a small surface area. Here, the deposition was carried out on P25 TiO₂ nanopowder with a specific surface area of about 54 m²g⁻¹, each of which was performed on 1.5 g of the material. As a consequence, the dose time was in the range of minutes. Our preliminary experiments showed that, for H₂O exposure, an increase of dose time from 5 min to 10 min did not result in any significant change in the Cu concentration. Therefore, a fixed H₂O dose time of 10 min was

employed to investigate the influence of Cu-precursor dose time, which was varied from 2.5 to 30 min, as demonstrated in Fig. 3.2a. In this figure, each data point represents the Cu concentration obtained after 10 ALD cycles. The results demonstrated that the Cu concentration increased rapidly when the Cu-precursor dose time increased from 2.5 min to 15 min. Thereafter, a further increase of dose time up to 30 min only resulted in a small increase in Cu concentration (i.e., from 4.6 % to 4.8 %). This indicates a saturation that represents the self-limiting characteristic of ALD. Furthermore, in the saturating regime (i.e., Cu-precursor dose time of 15 min and H₂O dose time of 10 min), Cu concentration increased linearly with the number of ALD cycles (Fig. 3.2b). This linear relationship, in conjunction with the self-limiting characteristics, reflects the ALD growth mode of Cu₂O, which allows tailoring of the Cu concentration by varying the number of ALD cycles.

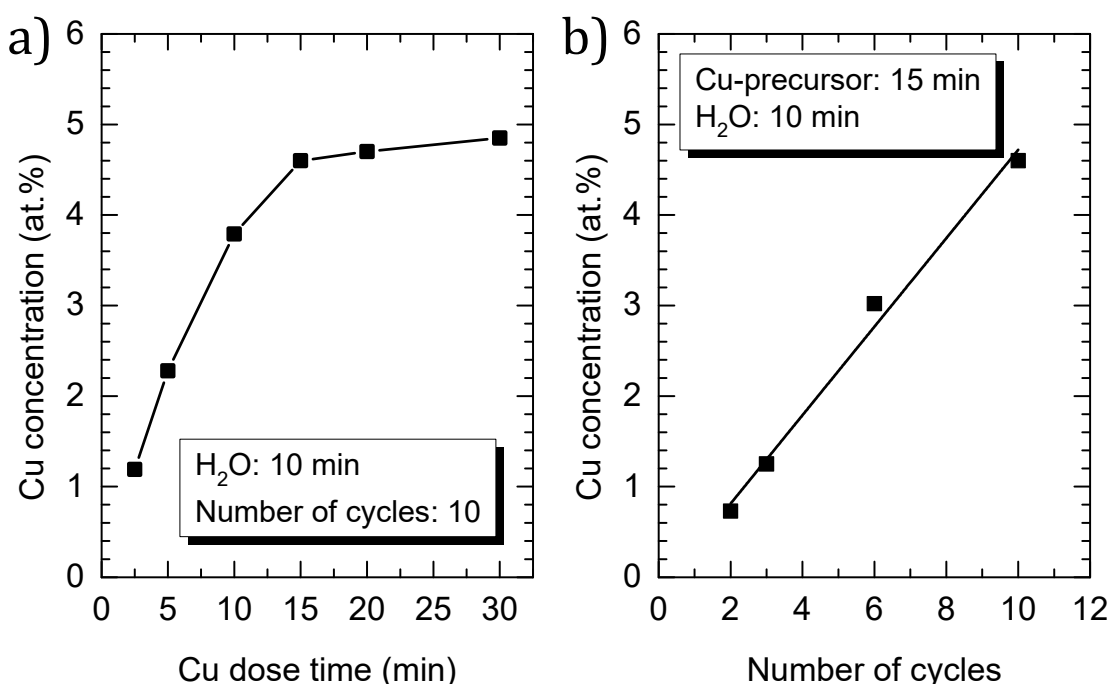

Figure 3.2: Cu concentration as a function of Cu(I)(hfac)(TMVS) dose time at a fixed H₂O dose time of 10 min (a), and Cu concentration as a function of the number of ALD cycles with the Cu-precursor and H₂O dose times of 15 min and 10 min, respectively (b).

3.3.2. Photocatalytic performance of Cu₂O/TiO₂ photocatalysts

RhB was used as a model pollutant for investigating the photocatalytic performance of the photocatalysts. Prior to the irradiation, the RhB/photocatalyst suspension was stirred continuously in the dark until the adsorption/desorption equilibrium was achieved, which was found in the range of 10 – 15 min (Fig. S3.1). During this stage, we observed that surface modification by Cu₂O slightly enhanced the adsorption of the dye molecules on the catalyst surface (ca. 5 – 7 %, Fig. S3.1). However, under the UV

irradiation, a small amount of Cu_2O could significantly alter the degradation rate of the organic pollutant, as demonstrated in Fig. 3.3a. Particularly, for the pristine TiO_2 , 90 % of the RhB was degraded after 30 min of irradiation. With the presence of Cu_2O at a Cu atomic percentage of 0.4 %, the degradation time was significantly reduced (i.e., 10 min). From the kinetic plots presented in Fig. 3.3b, which were derived from the degradation curves (Fig. 3.3a),⁷⁵ the apparent first-order kinetic constants (i.e., K_{app}) that represent the degradation rate of RhB were determined and plotted in Fig. 3.3c. It was found that the degradation rate obtained for the catalyst with 0.4 % Cu was more than twofold higher than that for the pristine P25 TiO_2 (i.e., 0.123 and 0.055 min^{-1} , respectively). With increasing the Cu concentration, the degradation rate continuously decreased. For the $\text{Cu}_2\text{O}/\text{TiO}_2$ with 1.2 % Cu, the degradation rate was nearly identical to that of the pristine TiO_2 , whereas, at a higher concentration, the photocatalytic activity was lower. The decreasing photocatalytic performance with increasing Cu_2O concentration could be due to the light-shielding effect, in which the presence of Cu_2O on the surface screens the light absorption of TiO_2 .⁵⁷ We emphasize that ALD of Cu_2O on TiO_2 with 0.4 % Cu requires only 1 ALD cycle and the process carried out in a fluidized bed reactor allows to perform the deposition on multigram TiO_2 powder. Moreover, the obtained product does not need any post-treatment process such as washing, drying or annealing that is commonly required in wet-chemistry methods.^{33, 46, 54, 58-60} Therefore, our technique provides a fast, scalable, and efficient route for TiO_2 surface modification to improve photocatalytic performance.

Figure 3.3: Photodegradation of RhB by P25 TiO_2 and $\text{Cu}_2\text{O}/\text{TiO}_2$ photocatalysts as a function of irradiation time (a) and the corresponding kinetic plots (b), from which the first-order kinetic constants were determined and plotted (c).

The improved photocatalytic performance by depositing Cu_2O was also observed for the photodegradation of methyl orange (MO) and methylene blue (MB). Fig. 3.4a demonstrates the degradation of MO and MB by pristine TiO_2 (the closed symbols)

and Cu₂O/TiO₂ with 0.4 % Cu (the open symbols). For comparison, the degradation of RhB (the dotted curves) is also included. The results show that the degradation of MO was enhanced 2.5 times, whereas an enhancement of 1.7 times was achieved for the degradation of MB (Fig. 3.4b). This further confirms the excellent photocatalytic properties of Cu₂O/TiO₂ over TiO₂.

Figure 3.4: Degradation of MO and MB by pristine TiO₂ and Cu₂O/TiO₂ (0.4 % Cu) photocatalysts (a) and the corresponding degradation rate constants (b). The data for RhB degradation are included for comparison. The arrows in (a) show the change of the photodegradation curves from the TiO₂ to the Cu₂O/TiO₂.

3.3.3. Roles of holes in the photodegradation of RhB by Cu₂O/TiO₂ photocatalyst

It has been demonstrated that the photodegradation of organic pollutants by TiO₂-based photocatalysts commonly proceeds via two routes: direct surface oxidation and OH* radical oxidation (i.e., indirect oxidation).⁷⁶⁻⁸⁰ The direct oxidation occurs when an

organic molecule strongly interacts with the catalyst surface and absorbs the photogenerated holes that eventually leads to the hydrolysis.^{76, 79} The indirect oxidation is caused by OH* radicals that are generated by the oxidation of H₂O. Many studies have proved that the degradation of organic pollutants is mainly mediated by OH* radicals.⁸¹ Nevertheless, other studies have also shown a significant contribution of the direct surface oxidation.⁸² In this work, the roles of photogenerated carriers were investigated by using scavengers, i.e., EDTA for holes⁸² and KClO₃ for electrons.⁸³ We found that the presence of electron scavenger KClO₃ enhanced the degradation of RhB (K_{app} increased from 0.122 to 0.219 min⁻¹), while the presence of hole scavenger EDTA significantly diminished the degradation (K_{app} decreased from 0.122 to 0.006 min⁻¹) (Fig. 3.5). This emphasizes the prominent role of holes in the photocatalytic reaction. Since holes can facilitate both direct oxidation and indirect oxidation (i.e., via OH* radical generation), their role was further elucidated by using other scavengers: DMSO and methanol. It has been demonstrated that DMSO scavenges OH* radicals but not holes,^{82, 84} while methanol can scavenge both holes and OH* radicals.^{82, 85} Therefore, using these scavengers, the contribution of direct oxidation (i.e., directly caused by holes) and indirect oxidation (i.e., caused by OH*) can be evaluated. The results show that when both holes and OH* radicals were scavenged, virtually no degradation was observed ($K_{app} = 0.003$ min⁻¹). When only OH* radicals were scavenged, the degradation was considerably diminished ($K_{app} = 0.052$ min⁻¹). This suggests that direct oxidation contributes considerably to the degradation of RhB. We note that when the concentration of DMSO was increased from 0.05 to 0.2 mmol, no significant change of the degradation was found (Fig. S3.2). In addition, the self-degradation and the degradation of RhB caused by the scavengers under UV irradiation (i.e., without catalysts) were inconsiderable (Fig. S3.3). Therefore, we conclude that the degradation of RhB by the Cu₂O/TiO₂ photocatalysts was caused by both direct surface oxidation and indirect oxidation.

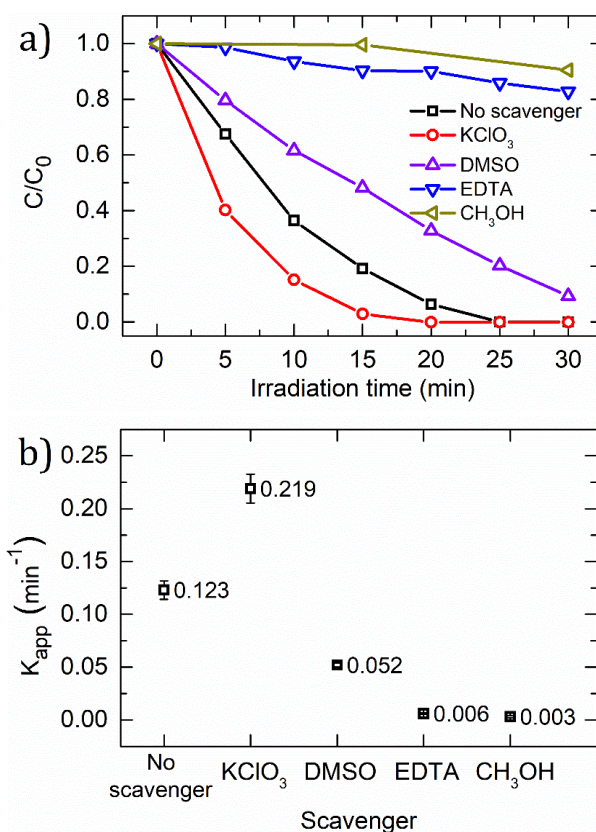

Figure 3.5: Influence of scavengers on the photodegradation of RhB by Cu₂O/TiO₂ (0.4 % Cu) photocatalysts (a): KClO₃ as electron scavenger, EDTA as hole scavenger, DMSO as OH^{*} radical scavenger, and CH₃OH as both OH^{*} radical and hole scavenger; the K_{app} values were determined from the corresponding degradation curves and plotted (b).

3.4. CONCLUSION

In conclusion, we have demonstrated ALD of Cu₂O using Cu(I)(hfac)(TMVS) and water at 250 °C, which was carried out in a fluidized bed reactor operating at atmospheric pressure. This provided a fast, scalable, and efficient route for TiO₂ surface modification to improve photocatalytic performance. The technique enabled the deposition of ultrasmall Cu₂O clusters with a low loading (i.e., 0.4 % for 1 ALD cycle), a narrow particle size distribution and an average size in the range of 1.3 – 1.5 nm on P25 TiO₂ nanoparticles. The self-limiting characteristics and the linear growth of ALD were achieved, which allowed us to control the amount of Cu₂O deposited on TiO₂ by varying the number of ALD cycles. At a Cu concentration of 0.4 %, the photocatalytic performance of TiO₂ was significantly enhanced, i.e., 2.2 times for RhB, 2.5 times for MO, and 1.7 times for MB. With increasing Cu concentration, the photocatalytic activity decreased; at a Cu concentration of 1.7 %, the photocatalytic activity of Cu₂O/TiO₂ was lower than that of pristine TiO₂. The roles of carriers were studied by investigating the influence of photogenerated carriers and radical scavengers on the degradation of RhB. It was found that both the direct surface oxidation and indirect oxidation by OH^{*} radicals contributed significantly to the photodegradation.

APPENDIX

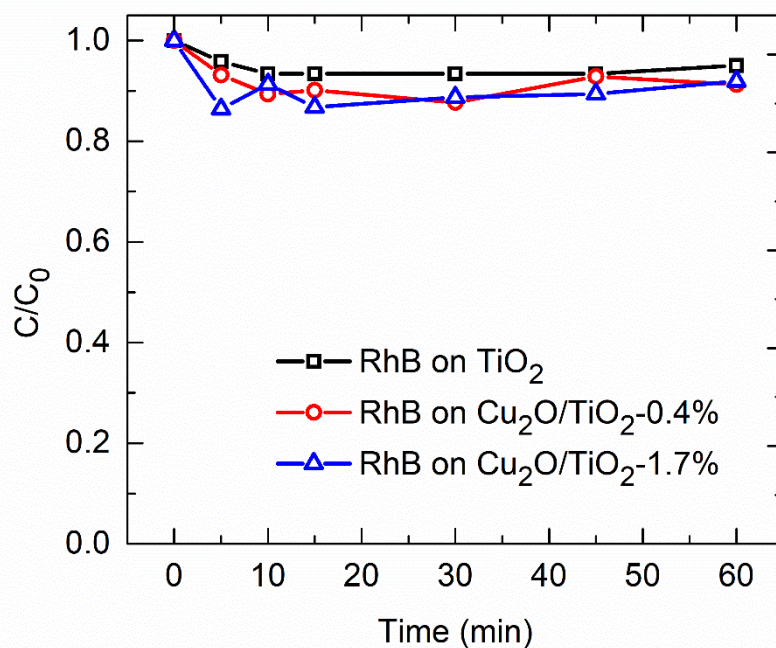

Figure S3.1: Adsorption of RhB on the surface of TiO_2 and $\text{Cu}_2\text{O}/\text{TiO}_2$ under no irradiation condition (in the dark). The results indicated that the adsorption/desorption equilibrium was obtained after 15 min and the presence of Cu_2O slightly enhanced the adsorption of RhB (ca. 5–7 %).

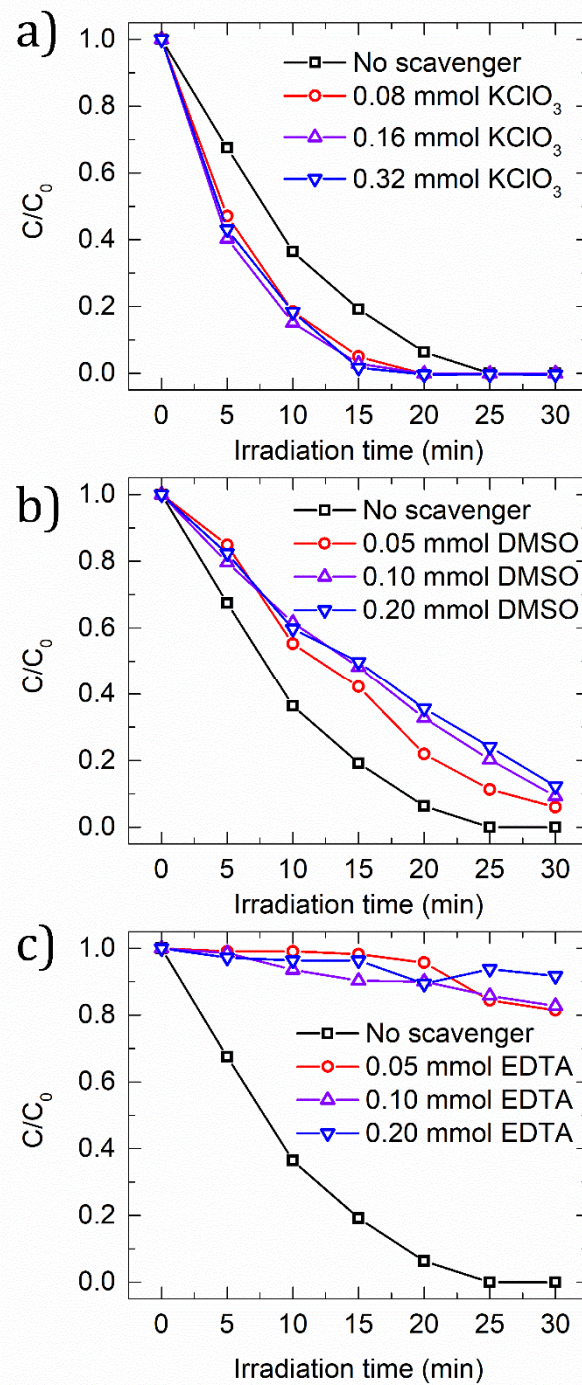

Figure S3.2: Degradation of RhB by $\text{Cu}_2\text{O}/\text{TiO}_2$ photocatalyst with Cu concentration of 0.4 at.% in the presence of scavengers with different concentrations: KClO_3 (a), DMSO (b) and EDTA (c).

Figure S3.3: Self-degradation curves of RhB (i.e., without catalysts) under UV-irradiation with or without the presence of scavengers. The results indicated the inconsiderable degradation of RhB after 90 min of irradiation.

Tuning the photocatalytic activity of TiO₂ nanoparticles by ultrathin SiO₂ films grown by low-temperature atmospheric pressure atomic layer deposition

4

This work demonstrates a feasible and efficient route for the synthesis of noble-metal free TiO₂-based photocatalysts with an enhanced activity and tunable photocatalytic properties. We employed atomic layer deposition to deposit ultrathin SiO₂ layers on P25 TiO₂ nanoparticles, which was carried out in a fluidized bed reactor working at atmospheric pressure using SiCl₄ and H₂O as precursors. This enabled the deposition of SiO₂ at 100 °C with the ability to control the thickness at the sub-nanometer level. We observed that by controlling the thickness of the SiO₂ in a very narrow range, i.e., below 2 nm, the photocatalytic activity of TiO₂ could be strongly enhanced or significantly diminished. Namely, an enhancement was obtained for the SiO₂ with a thickness of below 1.4 nm, in which the layer with a thickness of about 0.7 nm exhibited the highest photocatalytic activity, whereas, above 1.4 nm, the photocatalytic activity was significantly attenuated.

4.1. INTRODUCTION

For a few decades, since Fujishima and Honda discovered the photocatalytic splitting of water on TiO₂ electrodes¹, enormous efforts have been devoted to the development of TiO₂ photocatalysis. Owing to its excellent photocatalytic properties, high structural and chemical stabilities, low environmental impact, abundance in nature, and especially its suitable flat band potential for various redox reactions, TiO₂ has been widely used in various applications in environmental and energy-related fields, such as air purification, water treatment and hydrogen production.²⁻⁷ However, due to its large bandgap (i.e., ~3.2 eV), TiO₂ does not harvest efficiently sunlight that provides the highest photon flux in the visible and infrared regions.⁸ In addition, the rapid recombination of photogenerated electrons and holes is a limiting factor in achieving high photocatalytic efficiencies^{6,9}. Therefore, to improve light harvesting and to reduce charge recombination, electronic structure and surface properties of TiO₂ are usually modified.

The electronic modification of TiO₂ is commonly realized by doping the host material with other elements to form energy levels in the bandgap of TiO₂.^{3, 10-13} This consequently reduces the bandgap and enables the absorption of photons with lower energies.^{6, 14-17} In contrast, surface modification commonly promotes the charge transfer between the TiO₂ and the deposited materials, which can reduce the charge recombination¹⁴. In this case, the surface of TiO₂ is engineered by coupling with a thin film or nanoclusters of other materials.¹⁸⁻³¹ Due to their high catalytic activities, noble metals are most popularly used.^{19-21, 32-33} In addition to promoting the electron transfer due to their lower Fermi levels with respect to the conduction band of TiO₂³⁴⁻³⁶, noble metals can also act as co-catalysts, providing further catalytic enhancement.¹⁴ For instance, the surface modification of TiO₂ nanoparticles by Pt nanoclusters could significantly improve the photocatalytic activity of TiO₂ toward the degradation of Acid Blue 9.³⁷ Enhancement of photocatalytic performance was also observed for the TiO₂ modified with nanoclusters of Au, Ag, and Cu.²²⁻²⁵ Nevertheless, the use of noble metal may reduce the stability of the catalysts due to the oxidation at the metal/TiO₂ interface when exposed to UV-irradiation. This can create electron-hole recombination centers that affect the photocatalytic efficiency.³⁸ In addition, due to their high cost, the use of noble metals is not desirable. Therefore, the surface modification of TiO₂ by metal oxides such as CuO, Cu₂O, Fe₂O₃, CeO₂, MnO₂, and MgO has recently been more attractive.²⁶⁻³¹

Given its large bandgap (~9 eV), silicon dioxide (SiO₂) is an excellent dielectric that has been a key material in the microelectronic industry.³⁹ The good electrically insulating nature of SiO₂ also makes it the material of choice for mitigating the photocatalytic activity of TiO₂.⁴⁰⁻⁴³ This is due to the fact that a thin SiO₂ layer can effectively block the transport of photogenerated electrons and holes to the catalyst surface, diminishing the photocatalytic reactions.⁴⁰ Nevertheless, many studies have also shown that the coupling with SiO₂ can enhance the photocatalytic activity of TiO₂,

which has been utilized in various applications such as degradation of organic pollutants and bacteria, and CO₂ capture.⁴⁴⁻⁶⁰ Generally, the enhancement or suppression of photocatalytic activity strongly depends on the concentration (i.e., in the case of TiO₂-SiO₂ mixture) or the thickness (i.e., in the case of TiO₂/SiO₂ core/shell structure) of SiO₂. For example, for the TiO₂/SiO₂ core/shell structure, a thin layer of SiO₂ with a thickness of about 1–2 nm can effectively diminish the photocatalytic activity of TiO₂.^{43, 61} Therefore, in order to achieve an enhancement, a thinner layer is needed. This requires a synthesis method that allows controlling the thickness of the coating layer at the sub-nanometer level. In this regard, atomic layer deposition (ALD) is an excellent candidate. This is a gas-phase deposition technique that allows controlling the amount of deposited material down to the atomic scale, which has been utilized for the deposition of various materials.⁶²⁻⁶³

In this work, we employ ALD to deposit ultrathin SiO₂ films on P25 TiO₂ nanoparticles to realize a TiO₂/SiO₂ core/shell structure and investigate their photocatalytic properties. The SiO₂ ALD is carried out in a fluidized bed reactor (FBR) operating at atmospheric pressure, using silicon tetrachloride (SiCl₄) as the precursor and H₂O as the co-reactant. We demonstrate that this ALD process enables the deposition of SiO₂ at 100 °C. This deposition temperature is significantly lower than the typical temperature range (i.e., 300–420 °C) for conventional SiO₂ ALD using SiCl₄ and H₂O.⁶⁴⁻⁶⁶ Using ALD, we are able to control the thickness of the SiO₂ at the sub-nanometer level, which allows studying its influence on the photocatalytic activity of the TiO₂/SiO₂ photocatalysts. It is found that enhancement is obtained for the SiO₂ coating with a thickness of below 1.4 nm, in which the layer with a thickness of about 0.7 Å exhibits the highest photocatalytic activity. Above 1.4 nm, the photocatalytic activity is significantly attenuated. As a consequence, by varying the thickness of the SiO₂ coating in a very narrow range, i.e., below 2 nm, the photocatalytic activity of TiO₂ can be altered from enhancement to suppression, providing a feasible and efficient route to tune the photocatalytic activity of TiO₂ without the use of noble metals.

4.2. EXPERIMENTAL SECTION

4.2.1. Preparation of TiO₂/SiO₂ core/shell photocatalysts

The deposition of SiO₂ on TiO₂ nanoparticles was carried out in a fluidized bed reactor (FBR) operating at atmospheric pressure, as described elsewhere.⁶⁷ Degussa P25 TiO₂ (mean diameter of 21 nm and specific surface area of 54 m²g⁻¹) was purchased from Evonik Industries (Hanau, Germany). Silicon tetrachloride (SiCl₄) contained in a stainless steel bubbler was provided by Akzo Nobel HPMO (Amersfoort, the Netherlands). Pressurized nitrogen (99.999 vol.%) was used as the carrier gas. For

each experiment, 1.5 g of powder was used. The powder is fluidized by an N₂ gas flow of 0.5 L min⁻¹, which was introduced through the distributor plate placed at the bottom of the glass column. An ALD cycle consisted of alternating exposures of the TiO₂ powder to SiCl₄ vapor (1 min), followed by an N₂ purging step (3 min), the deionized water vapor (3 min), and finally an N₂ purging of 8 min. The deposition temperature was set at 100 °C. During the deposition, a temperature variation of ±5 °C was observed.

4.1.1. Characterization

The morphology of the TiO₂/SiO₂ particles was characterized by transmission electron microscopy (TEM) using a JEOL JEM1400 transmission electron microscope. X-ray photoelectron spectroscopy (XPS) was employed to investigate elemental compositions and bonding states of the TiO₂/SiO₂ catalysts using a ThermoFisher K-Alpha system (photon energy of 1486.7 eV). The peak positions were calibrated by using the C 1s peak at 284.8 eV as the reference.

The atomic concentration of the deposited SiO₂ was determined using instrumental neutron activation analysis (INAA). For each measurement, 100 mg powder was loaded into high purity polyethylene capsules. The samples and a reference sample were irradiated at a constant neutron flux. All reactors used for neutron activation employed uranium fission, which provides a neutron flux (kinetic energy less than 0.5 eV) in the order of 10¹² cm⁻²s⁻¹. Upon irradiation, a neutron can be absorbed by the target nucleus (i.e., Si), forming a radioactive nucleus. The nuclear decay of the radioactive nuclei produces Gamma rays, which can be detected by the INAA detectors, from which the Si loading was determined.

The specific surface area (SSA) of the powder was determined by the BET method using a Micromeritics Tristar II at 77 K. For each measurement, 160 mg of the powder was used. All the samples were annealed in N₂ at 150 °C for 16 hours prior to the measurements. Data analysis was performed using Microactive software V3.02. The BET SSA was determined by fitting of the data points in the P/P₀ = 0.05–0.225 region.

The photodegradation of Rhodamine B (RhB) in aqueous solution was used to evaluate the photocatalytic activity of the TiO₂/SiO₂ photocatalysts. In each experiment, 10 mg of the catalyst was added to 80 mL RhB solution (RhB concentration of 10 mg L⁻¹) contained in a 200-ml glass beaker (diameter of 8 cm). The suspension was continuously stirred in the dark for 30 min to obtain the adsorption/desorption equilibrium, which was then exposed to UV-radiation generated by a mercury lamp (25 W, 620 lux at the reactor surface) for different exposure times. After separating the solid catalyst by centrifuging, the solution was analyzed by UV-visible spectroscopy using a Jenway's 6800 double beam spectrophotometer to determine the RhB residual concentration.

4.2. RESULTS AND DISCUSSION

4.2.1. Morphology, structure and elemental composition of the TiO₂/SiO₂ photocatalysts

The reactions between SiCl₄ and H₂O in ALD of SiO₂ are based on the ligand exchange between the functional groups, i.e., –Cl and –OH, on the surface, which requires a relatively high temperature, typically in the range of 300–420 °C.⁶⁴⁻⁶⁶ For lower deposition temperatures, the presence of a catalyst, such as ammonia (NH₃) or pyridine (C₅H₅N), is commonly needed.⁶⁸⁻⁶⁹ Nevertheless, the SiCl₄/H₂O ALD process carried out in a fluidized bed reactor operating at atmospheric pressure in this work enabled the growth of SiO₂ at 100 °C, which is significantly lower than the deposition temperature reported in the literature.⁶⁴⁻⁶⁶ Previous research demonstrated that high partial pressure of the reactants plays a crucial role and enables deposition at lower temperature.⁷⁰ TEM images presented in Figs. 4.1a–d demonstrate the deposition of TiO₂/SiO₂ nanoparticles with a core/shell structure. From the TEM images, the thickness of the SiO₂ layer is determined, whereas the Si atomic concentration (Si at. %) is measured by INAA. The plots of SiO₂ thickness and Si at.% as a function of the number of ALD cycles exhibit a linear dependence (Fig. 4.1e) that represents the linear-growth regime of ALD.⁷¹ In this regime, a growth-per-cycle (GPC) of approximately 0.5 Å is obtained, which is slightly lower than the GPC of the SiO₂ ALD reported in the literature (i.e., 0.7–1.1 Å).⁶⁴⁻⁶⁵ In addition, the small variation of the GPC obtained for different SiCl₄ exposure times (i.e., from 5 s to 120 s) shown in Fig. 4.1f reflects the self-saturating behavior of ALD.⁷¹ This self-limiting behavior, in combination with the linear growth, provides the ability to control the thickness of the SiO₂ layer at the sub-nanometer level by controlling the number of cycles. This allows us to investigate the influence of the SiO₂ thickness at the ultrathin regime (i.e., < 2 nm) on the photocatalytic activity of TiO₂.

Figure 4.1: TEM images of TiO₂ nanoparticles coated with SiO₂ films grown at 100 °C for 8 cycles (a), 12 cycles (b), 30 cycles (c) and 40 cycles (d). The SiO₂ film thickness (□) and the Si atomic concentration (○) as a function of the number of cycles are plotted in (e). The plot in (f) shows the Si atomic concentration obtained for 12 ALD cycles in which the SiCl₄ pulse time is varied from 5 to 120 s while the pulse time of H₂O vapor is fixed at 300 s.

The specific surface area (SSA) of the TiO₂ powders before and after coating with SiO₂ is determined by BET method. An SSA of 54.5 m² g⁻¹ is obtained for the uncoated P25 TiO₂, which is consistent with the SSA value provided by the supplier. No considerable change is observed for the total SSA obtained for the TiO₂ powder coated with SiO₂ for different numbers of ALD cycles, as shown in Fig. 4.2 (the squares).

However, using the T-method⁷², the analysis of the isothermal curves reveals the presence of micropores in the SiO₂ films whose volume and SSA increase with the number of cycles (Fig. 4.2, the stars and the triangles). The external SSA of the powders is determined from the total SSA and the SSA of the micropores, showing a slight decrease with increasing the number of ALD cycles (Fig. 4.2, the circles). This decrease is attributed to the increase in particle size caused by the SiO₂ coating layer.

Figure 4.2: The total SSA (\square), micropore SSA (∇), micropore volume ($*$) and external SSA (O) of the TiO₂ powder coated with SiO₂ for different numbers of ALD cycles as determined by BET.

The results obtained from the XRD characterization show the amorphous state of the SiO₂ films, even after annealing at 500 °C for 16 hours (Fig. S4.1, *Supporting Information*). The XPS spectra of the C 1s, Ti 2p, O 1s and Si 2p core-levels of the uncoated TiO₂ and TiO₂/SiO₂ are presented in Fig. 4.3. We note that in order to eliminate the influence of the peak shift due to charging effects, the peak positions are calibrated by referencing the C–C peak of the C 1s to the binding energy (BE) of 284.8 eV (Fig. 4.3a).⁴⁷ For the uncoated TiO₂, the two peaks at BE = 464.2 eV (Ti 2p_{1/2}) and BE = 458.6 eV (Ti 2p_{3/2}) in the top spectrum of Fig. 4.3b reflect a doublet state of Ti(IV) 2p that arises from the spin-orbit coupling. These two peaks in conjunction with the peak at BE = 529.7 eV of O 1s (Fig. 4.3c, the top spectrum) represent the Ti–O bond of TiO₂ (hereafter designated as O–Ti).^{47, 73-74} The peak at BE = 457.4 eV in the Ti 2p top spectrum (Fig. 4.3b) could represent the Ti 2p_{3/2} of the Ti(III) compounds (e.g., Ti₂O₃, oxygen vacancies, etc.)⁷⁴, whereas the broad peak at 532.0 eV in the O 1s top spectrum (Fig. 4.3c) is attributed to the chemisorbed hydroxyl groups (i.e., OH groups) on the surface⁵⁴. The presence of these OH groups is confirmed by the FTIR spectra (Fig. S4.2, *Appendix*).

Figure 4.3: Core-level XPS spectra of C 1s (a), Ti 2p (b), O 1s (c) and Si 2p (d) of the uncoated TiO₂ (top spectra) and TiO₂ coated with SiO₂ for 12 ALD cycles (bottom spectra).

For TiO₂/SiO₂, the peak at BE = 532.4 eV (O 1s, Fig. 4.3c) and the peak at BE = 103.0 eV (Si 2p, Fig. 4.3d) represent the Si-O bond (hereafter designated as O-Si).⁷⁵⁻⁷⁶ The binding energy difference between the Si 2p and the O 1s of the O-Si

bond is 429.4 eV, which is consistent with the binding energy difference of the Si–O bond of SiO₂ (i.e., 429.3–429.4 eV).⁷⁵⁻⁷⁶

Furthermore, after coating with SiO₂, the Ti 2p and O 1s peaks of the O–Ti bond exhibit remarkable shifts (i.e., 0.4 eV for Ti 2p and 0.5 eV for O 1s) toward the higher binding energy (Fig. 4.3b and Fig. 4.3c). This shift is evidence of the formation of Ti–O–Si linkages at the interface between TiO₂ and SiO₂ and arises from the difference in electron negativity between Si (1.90), Ti (1.56) and O (3.44)^{47,77}. The presence of the linkages is also indicated by the peak at 531.8 eV in the O 1s spectrum (Fig. 4.3c).⁷⁸⁻⁷⁹ The XPS analyses confirm the presence of SiO₂, which is additionally supported by the FTIR spectra (Fig. S4.2, *Supporting Information*).

4.2.2. Photocatalytic properties of the TiO₂/SiO₂ core/shell nanoparticles

The adsorption of RhB on the photocatalysts before UV-irradiation was examined by monitoring the change of RhB concentration while stirring the catalyst/RhB aqueous mixture in the dark. This study was carried out for the uncoated TiO₂ and the TiO₂ coated with SiO₂ for 2 and 12 ALD cycles; the results are presented in Fig. 4.4a. Analogous behavior is observed for all samples, which shows a rapid decrease of the RhB concentration in the first 10 min caused by the adsorption of RhB on the surface of TiO₂. Thereafter, no considerable change of the RhB concentration is observed, indicating that the adsorption-desorption equilibrium has been established. The similar adsorption of RhB on TiO₂ and the SiO₂-coated TiO₂ suggests that the adsorption of RhB molecules is not enhanced by the SiO₂ layer, which is in contrast with the results reported in the pioneering work of Anderson and Bard, in which an enhanced adsorption of the organic molecules on the catalyst surface due to SiO₂ was observed^{45, 80}. However, the SiO₂ layer strongly alters the photodegradation of RhB under UV-light irradiation, as shown in Fig. 4.4b. Particularly, for the uncoated TiO₂, approximately 90% of the RhB is degraded after 30 min irradiation. For the TiO₂/SiO₂, the photodegradation exhibits a strong dependence on the thickness of the SiO₂ coating layer, which can be estimated by the kinetics of the photodegradation reaction described by equation:⁸¹

$$\ln(C_0/C) = k_{\text{app}} \cdot t, \text{ or } C = C_0 \cdot \exp(-k_{\text{app}} \cdot t) \quad (1)$$

Figure 4.4: Adsorption behavior of RhB on the uncoated TiO₂ and the TiO₂ coated with SiO₂ for 2 and 12 ALD cycles (a), the degradation of RhB as a function of irradiation time (b) and the corresponding kinetic plots (c), from which the first-order kinetic k_{app}

where k_{app} represents the degradation rate, which is commonly referred as the apparent first-order kinetic constant. The plots $\ln(C_0/C)$ vs. t are shown in Fig. 4.4c, from which the k_{app} values are determined and plotted in Fig. 4.4d. For the uncoated TiO₂, a k_{app} of $55.2 \times 10^{-3} \text{ min}^{-1}$ is obtained. The coating of TiO₂ by SiO₂ initially results in an increase of k_{app} with increasing the number of ALD cycles, reaches the maximum value of $95.6 \times 10^{-3} \text{ min}^{-1}$ at 8 ALD cycles, which is corresponding to a SiO₂ film thickness of about 0.7 nm (Fig. 4.1a). Hereafter, k_{app} gradually decreases to $64.6 \times 10^{-3} \text{ min}^{-1}$ for 20 ALD cycles, which is slightly higher than the k_{app} obtained for the uncoated TiO₂. A further increase of the number of cycles to 30 and 40 results in a rapid drop of k_{app} to $8.4 \times 10^{-3} \text{ min}^{-1}$ and $4.3 \times 10^{-3} \text{ min}^{-1}$, respectively. The low k_{app} values achieved for 30 and 40 ALD cycles, which correspond to the SiO₂ thickness of 1.4 and 1.8 nm (Figs. 4.1c-d), respectively, indicate that the photocatalytic activity of TiO₂ is strongly suppressed. Furthermore, photocatalytic tests under visible light showed no catalytic activity, indicating that self-sensitiation plays a negligible role in the photocatalytic mechanism and the degradation of RhB is purely based on the photocatalytic activity of the modified P25 particles.

The results show that by varying the thickness of the SiO₂ layer, the photocatalytic activity of TiO₂ can be tuned. In particular, an enhancement can be achieved by coating the TiO₂ with a SiO₂ layer thinner than 1.4 nm, in which a layer of 0.7 nm provides the highest photocatalytic activity. For SiO₂ layers thicker than 1.4 nm, the photocatalytic activity of TiO₂ is significantly diminished. It can be seen that the photocatalytic activity of TiO₂/SiO₂ powders is highly sensitive to the thickness of the SiO₂ layer. A small variation of the thickness in a very narrow range (i.e., below 2 nm) may entirely alter the photocatalytic property of the material from enhancement to suppression. As a consequence, tuning the catalytic activity of TiO₂ by SiO₂ requires precise control of the coating thickness. This can be a major challenge to conventional synthesis techniques such as sol-gel and hydrothermal. However, as demonstrated, the ALD process reported in the present work has shown great advantages in controlling the thickness of SiO₂ down to the sub-nanometer level, providing the ability to tailor the photocatalytic properties of TiO₂ for various applications. For instance, whereas the enhanced activity is highly desirable for photocatalysis, the suppression is of great interest for the applications of TiO₂ in pigment, paint, and cosmetic industries.^{7, 82}

4.3. CONCLUSIONS

In conclusion, ALD using SiCl₄ and H₂O carried out in a fluidized bed reactor operating at atmospheric pressure enables the deposition of SiO₂ on P25 TiO₂ nanoparticles at 100 °C, which is significantly lower than the deposition temperature in conventional ALD processes. The linear-growth regime with a growth-per-cycle of 0.5 Å is achieved, and the self-limiting characteristic of the SiO₂ ALD is demonstrated. It is found that the photocatalytic activity of SiO₂-coated TiO₂ particles is strongly dependent on the thickness of the SiO₂ layer, which takes place in a very narrow thickness range, i.e., below 2 nm. Particularly, a SiO₂ layer below 1.4 nm can significantly enhance the photocatalytic activity of TiO₂, in which the highest enhancement is obtained at a thickness of about 0.7 nm. SiO₂ layers above 1.4 nm strongly diminish the photocatalytic activity. As a consequence, by controlling the thickness of SiO₂ coating at the sub-nanometer level, the photocatalytic property of TiO₂ is tuned from an enhancement to a suppression. Therefore, our work has demonstrated a feasible and efficient route not only for the synthesis of noble-metal free TiO₂-based photocatalysts with enhanced activity but also for tuning the photocatalytic properties. Moreover, the low-temperature ALD process is a valuable asset that can enable the application of SiO₂ coating on temperature-sensitive materials such as polymers and organic materials.

APPENDIX

Figure S4.1: XRD patterns of the initial TiO₂ powder (3), the TiO₂ coated with SiO₂ for 30 ALD cycles before (2) and after (1) annealing at 500 °C for 16 hours in air. The results show that the XRD peaks of the P25 TiO₂ are unaffected after coating with SiO₂, even after the annealing. This suggests the amorphous state of the SiO₂ layer. The measurements were carried using a PANalytical X-pert Pro diffractometer with Cu K α radiation.

Figure S4.2: FTIR spectra of the uncoated TiO_2 (1), TiO_2 coated with SiO_2 for 12 ALD cycles (2) and 30 ALD cycles (3). The spectra show the presence of hydroxyl groups and physisorbed water for both uncoated and SiO_2 -coated TiO_2 in the spectral ranges of 3100–3600 cm^{-1} and 1550–1700 cm^{-1} , respectively. The peaks in the spectral range of 2280–2400 cm^{-1} represent the adsorbed CO_2 , which is only observed for the $\text{TiO}_2/\text{SiO}_2$. The peaks in the spectral range of 980–1275 cm^{-1} represent the Si–O–Si bonds, which are not observed for the uncoated TiO_2 . This is evidence of the presence of SiO_2 on the surface of TiO_2 .

Mechanistic insight into the improved photocatalytic degradation of dyes using TiO₂ (P25) nanoparticles with an ultrathin SiO₂ coating

5

The photocatalytic mechanism of TiO₂ (P25) nanoparticles coated with SiO₂ (SiO₂:P25) layers by atomic layer deposition has been studied. The formation of thin SiO₂ layers on P25 not only gives a photocatalytic improvement for the degradation of Rhodamine B (3.6-fold) and Acid Blue 9 (3-fold) but also changes the mechanism from direct oxidation of the pollutant at the surface of TiO₂ (P25) to a predominantly OH radical based degradation of the pollutants using SiO₂:TiO₂(P25). SiO₂ layers on TiO₂ improve the generation of OH radicals due to the more acidic Si-OH groups in combination with the facilitated charge separation at the TiO₂-SiO₂ interface. The degradation of differently charged dyes on the SiO₂:TiO₂(P25) surface demonstrates the independence of the adsorption properties on the photocatalytic improvement. Simultaneous degradation of two dyes demonstrated the advantage of SiO₂:TiO₂ (P25) being less selective and, therefore, may be better suited for general water purification.

5.1. INTRODUCTION

Photocatalysis undoubtedly has excellent potential for chemistry with several environmental applications, such as air purification and water cleaning. Since the first paper by Fujishima and Honda¹ almost 50 years ago, substantial progress has been made. However, further significant steps are required to come to the broad implementation of this technology. For the commonly used photocatalyst TiO₂, numerous studies have investigated the photocatalytic mechanism.²⁻¹¹ However, improved photocatalysts based on modifications of TiO₂ are often still lacking a clear description of the photocatalytic mechanism. This hampers the rational design of high-performance photocatalysts, where the combination of multiple materials could lead to significant activity improvement.

The photocatalytic activity is commonly improved by incorporating heteroatoms either in bulk or adding materials onto the surface, which enhances one or more properties important for photocatalysis. In heterogeneous photocatalysis for water treatment four different steps are essential for a reaction: 1) adsorption of reactants to the surface, 2) light absorption of the catalyst leading to excitation of an electron from the valence band (VB) to the conduction band (CB) 3) redox reactions of the reactants (pollutant, H₂O or O₂) on the surface to directly degrade pollutants or generate reactive oxygen species (ROS) and 4) desorption of the reactant from the surface. Upon light absorption with an energy higher than the bandgap, an electron (e⁻) is excited to the conduction band, leaving a hole (h⁺) back in the valence band. Excited electrons are able to reduce the dissolved O₂ in the water to a superoxide radical O₂^{*-}, further reacting to OH^{*} radicals, and subsequently attacking and degrading the pollutant. Moreover, holes in the VB are either able to oxidize the pollutant directly or react with water to form hydroxyl radicals OH^{*}, which subsequently attack the pollutant.¹²⁻¹³ In order to improve the performance of a photocatalyst, different strategies can be applied to optimize the properties involved in each step: 1) Increase the adsorption of the reactants to reduce mass transfer limitations, 2) absorb more light to generate more charge carriers or utilize the light better by preventing electron-hole recombination, 3) improve the formation of reactive oxygen species (OH^{*}, O₂^{*-}) to degrade pollutants faster, and 4) enhance the desorption of products to prevent surface poisoning.¹⁴⁻¹⁵

Photocatalysts containing both SiO₂ and TiO₂ were investigated widely in recent research. However, SiO₂ was mostly used as a substrate where TiO₂ was deposited onto since it is believed that SiO₂ due to its electronic properties will block the photocatalytic activity.¹⁶⁻²⁰ Reports indicate that by using SiO₂ as a substrate, the adsorption of pollutants is increased due to a change in the surface charge/zeta potential leading to an improvement in the photocatalytic activity.¹⁶⁻¹⁷ Only recently, studies of core/shell particles with TiO₂ and SiO₂ have elaborated on the photocatalytic activity of degrading organic pollutants.²¹⁻²⁵ Very thin layers of SiO₂ on TiO₂ are needed to observe an improvement in the photocatalytic activity. The reasons for the enhancement are ascribed to enhanced adsorption^{21-22, 26} and better charge transfer/improved charge separation²⁷⁻²⁹ or better desorption of the degradation products.²³⁻²⁴

However, an overall understanding with a clear insight into the predominant photocatalytic reaction pathway is still lacking.

In this chapter, we elucidate the photocatalytic mechanism of SiO₂ coated TiO₂ (P25) by evaluating the fundamental steps in photocatalysis for TiO₂ (P25) compared to SiO₂:TiO₂(P25). Applying the finding from our previous research³⁰ where atomic layer deposition allowed us to build up SiO₂ layer by layer due to its characteristic alternating gas phase exposures of metal precursor and oxidizer, resulting in a photocatalytic improvement for SiO₂ on TiO₂ (P25), the thus obtained materials will serve us to clarify the predominant photocatalytic pathways. By comparison of the degradation behavior of two oppositely charged pollutants, we elaborate on the importance of adsorption on the surface. Sacrificial agents and simultaneous degradation of two oppositely charged dye molecules gave insight into predominant photocatalytic pathways for the radical generation. For this purpose, we employ atomic layer deposition (ALD) to deposit ultra-thin layers of SiO₂ onto TiO₂ (P25) particles to obtain a model catalyst where we are able to investigate the photocatalytic mechanism in detail. This will open up the door for further developments of novel multi-component materials, where different functionalities linked to subsequent mechanisms steps could be added to further improve the catalytic activity.

5.2. EXPERIMENTAL SECTION

5.2.1. Materials synthesis

TiO₂ (P25) nanoparticles (mean diameter ~21 nm, specific surface area of ~54 m²g⁻¹ measured by BET) were purchased from Evonik Industries (Hanau, Germany). The powder was sieved prior to the ALD experiments with a 250 μm sieve to break or exclude larger agglomerates.

Silicon tetrachloride (SiCl₄) was purchased from Sigma-Aldrich and stored in a stainless steel bubbler for mounting into the ALD setup.

Acid Blue 9 (AB9), Rhodamine B (RhB), Methanol, and DMSO were purchased from Sigma Aldrich and were used without further purification.

Silicon dioxide was deposited on the P25 particles on a homebuilt ALD setup in a fluidized bed under atmospheric pressure based on a setup described elsewhere.³¹⁻³²

In brief, the P25 powder was placed in a quartz glass column (diameter 26 mm, height 500 mm), which was then placed on a vertical vibration table (Paja 40/40-24) to assist fluidization. SiO₂ layers were deposited using SiCl₄ and H₂O as precursors, which both were kept at room temperature in stainless steel bubblers. The reactor was heated to 100 °C by an IR lamp, and a temperature feedback controller was placed inside the powder bed throughout the deposition process. Different SiO₂ loadings were produced by applying up to 40 cycles using 30 s SiCl₄ exposure and a 30 s water pulse. The precursors were carried to the reactor by a flow of nitrogen (0.5 L/min) and the pulses

were separated by purging steps of nitrogen for 3 min and 8 min, respectively. Afterward, the samples were calcined at 500 °C for 2h in air in a Neytech Vulcan Benchtop furnace.

5.2.2. Materials characterization

For the ICP-OES analysis, approximately 30 mg of sample was destructed in 4.5 ml 30 % HCl + 1.5 ml 65 % HNO₃ + 0.2 ml 40% HF acid mixture using a microwave. The destruction time in the microwave was 60 min. After the destruction, the samples were diluted to 50 ml with Milli-Q and analyzed with ICP-OES 5300DV. For Ti analysis, the samples were also diluted 20 times.

TEM micrographs were acquired from a JEOL JEM1400 transmission electron microscope at 120 kV. As-deposited TiO₂-SiO₂ nanoparticles were suspended in ethanol and transferred to Cu transmission electron microscopy grids (3.05 mm in diameter, Quantifoil).

X-ray photoelectron spectra (XPS) were recorded on a ThermoFisher K-Alpha system using Al K α radiation with a photon energy of 1486.7 eV. The powder samples were immobilized on copper tape before loading into the XPS chamber. Scans were acquired using a 400 μ m spot size, 55 eV pass energy, and 0.1 eV/step with charge neutralization. The peak positions were analyzed by calibrating the C 1s peak at 285 eV. The background was subtracted using ThermoAvantage software, applying a *SMART* type background subtraction.

UV/Vis diffuse reflectance spectra (DRS) were recorded on a Lamda 900 spectrophotometer recording the reflectance of the samples from an incident wavelength of 250 nm to 600 nm. The bandgap was obtained using the corresponding Tauc plot.

Zeta-potential measurements were executed on a Malvern Zetasizer Nano. The zeta-potential was measured in a solution of Rhodamine B (12 mg/l_{aq}) and Acid Blue 9 (16 mg/l_{aq}) with a catalyst concentration of 1 g/l. Prior to the measurement, the sample was stirred for 15 min, dispersed with a Sonotrode (Dr. Hielscher GmbH) for 1 min, followed by 15 min stirring. After equilibrating for 5 min, the sample was measured at 25 °C. For error analysis, each dispersion was measured three times.

Diffuse reflectance infrared Fourier transform spectra (DRIFTS) were recorded on a Thermo Nicolet Nexus IR with the OMNIC software. The sample was heated and measured at 150 °C to reduce the influence of adsorbed water. KBr served as a background and was subtracted for each sample.

5.2.3. Photocatalytic testing

Photocatalytic testing was performed in a 100 ml cylindrical glass container (irradiation surface 11.3 cm²) with a 30 ml solution of Acid Blue 9 (16 mg/l, 20 μmol/l in deionized water) or Rhodamine B (12 mg/l, 25 μmol/l in deionized water) and 30 mg of catalyst powder. The test was executed in an Atlas SunTest XXL solar simulator equipped with 3 Xenon lamps (45 W/m²) to ensure homogeneous light distribution and simulating the sun's spectrum in both the UV and visible light range.³³ Multiple samples were irradiated simultaneously on a stirring plate (700 rpm) with multiple spots. The powder was dispersed by sonicating the dispersion with the powder for 10 min. Additionally, the dispersion was stirred in the dark for another 20 min in order to reach the adsorption-desorption equilibrium. 1 ml samples were taken after distinct times of irradiation and were then centrifuged, and the supernatant liquid was then analyzed using a UV/Vis spectrometer (Hach-Lange DR5000). The absorption was measured at 629 nm and 554 nm, which are the maxima for Acid Blue 9 and RhB, respectively, from which the dye concentration *C* was deduced. According to first-order kinetics, $\ln(C_0/C_t)$ was plotted vs. decomposition time and the slope of the linear regression represents the kinetic constant. Tests with sacrificial agents were executed in the same manner adding 175 μl (82 mmol/l) of DMSO or 100 μl (82 mmol/l) methanol to the solution.

5.3. RESULTS AND DISCUSSION

Figure 5.1: a) Loading of Si (wt %) vs. the number of ALD cycles; b) TEM image of SiO₂:TiO₂(P25) (1.7 wt % Si), layers of SiO₂ of around 1 nm thickness decorate the surface of P25 particles.

SiO₂ layers were deposited on P25 using atomic layer deposition. With this technique, we deposited SiO₂ up to 2.7 wt % Si (Fig. 5.1a) in a very conformal manner (Fig. 5.1b) where the Si loading (wt %) increases with the number of ALD cycles (Fig. 5.1a). The

higher growth per cycle for a low number of cycles arises from the better reactivity of SiCl₄ with the TiO₂ surface. The deposition could be proven by TEM, which exhibits a layer of SiO₂ around the P25 particle (Fig. 5.1b). Despite that in the TEM pictures, layer formation for high loadings can be clearly observed, the detection of ultrathin layers of SiO₂ for samples with very low loading remains difficult due to the resolution limit of the TEM. Moreover, a low number of cycles might cause porous or even incomplete coatings leaving the TiO₂ surface exposed to the environment. Additionally, for samples with a low number of SiCl₄/H₂O, XPS analysis reveals extensive contamination with Cl due to the incomplete reaction of SiCl₄ with water (Fig. S5.1). Post-annealing in air at 500 °C converted residual SiO_xCl_{4-2x} into SiO₂, as demonstrated by XPS (Fig. S5.2), eliminating the contamination arising from the deposition process. XRD revealed that P25 keeps its mixed crystalline anatase/rutile phase after annealing in air and that SiO₂ remained amorphous on the surface of TiO₂ (P25).³⁰ The photocatalytic degradation of both RhB and AB9 displays a major improvement with the deposition of SiO₂ layers onto P25 (Fig. S5.5, Fig. 5.2, RhB: 3.5-fold improvement for annealed 1.7 wt % SiO₂:TiO₂(P25), AB9: 3-fold improvement for annealed 1.7 wt % SiO₂:TiO₂(P25)). Moreover, while the post-treatment only insignificantly influences the photocatalytic activity of P25, it strongly influences the performance of SiO₂:TiO₂(P25). The Cl contamination has a significant negative impact on the photocatalytic activity with especially Acid Blue 9 (AB9) strongly adsorbing on the surface of the low loaded Si samples (Fig. S5.3). These chlorides in solution may arise from the reaction of water with the residual Cl in SiO_xCl_{4-2x} layer. Chloride contamination in solution results in a strong increase in the zeta potential of SiO₂.³⁴ This results in a more positive zeta potential, strongly increasing the adsorption of the negatively charge AB9 molecules. Additionally, chloride ions have been found capable of scavenging holes, leading to a decrease in photocatalytic activity.³⁵⁻³⁶ This demonstrates that a pure SiO₂ layer is highly beneficial for photocatalytic improvement. Therefore, for the subsequent experiments, the annealed samples have been used.

Figure 5.2: Kinetic constant for the photocatalytic degradation of a) RhB and b) AB9 using various loadings of Si, lighter shades represent the as-deposited samples.

Our previous research demonstrated a twofold enhancement for the degradation of Rhodamine B (RhB) with a loading of 1.9 wt % Si, followed by a total suppression of the photocatalytic activity for higher loadings (> 5 wt % Si).³⁰ Silicon dioxide – as an electric insulator with a bandgap of 9 eV – is not expected to have photocatalytic properties using the sun spectrum, due to insufficient photon energy to generate excited electrons and holes. This lack of charge transport in intrinsic SiO₂ explains the trend towards total suppression of the photocatalytic activity for higher loadings where the SiO₂ approaches the properties of pure SiO₂ as intrinsically photocatalytic inactive material. Higher loadings leading to thicker coatings additionally hinder the pollutants from reaching the active TiO₂ surface and blocking electron transport from the TiO₂ to the surface.³⁷ This explains the photocatalytic suppression of thick SiO₂ layers on P25. However, the reason for the photocatalytic enhancement due to an ultrathin SiO₂ layer on P25 particles and the predominant degradation pathways are still unresolved. We will now look at the activity increase for very low loadings using different tools to investigate the photocatalytic mechanism of a thin SiO₂ layer on P25 nanoparticles.

It is well known that SiO₂ surfaces have more acidic OH groups than TiO₂, which will result in a more negative zeta potential: the points of zero charge are about 3³⁸ and 6³⁹, respectively. Figure 5.3a shows the zeta potential for different loadings of SiO₂ on P25. It should be noted that the zeta potential was measured in the dye solutions to imitate the conditions used in the photocatalytic experiments. Uncoated P25 has a slightly positive zeta potential of 0-15 mV dependent on the dye in the solution. Upon deposition of SiO₂, the zeta potential decreases to approximately -40 mV for the samples with the highest SiO₂ loading, clearly indicating not only a change in the value but also a change from positive to negative values. This is a result of the difference of the isoelectric point (IEP) of SiO₂ (IEP = 3) versus TiO₂ (IEP = 6).^{18, 40} The zeta potential of the powders dispersed in the solution of AB9 is generally more negative than in a solution of RhB (Fig. 5.2a), indicating that AB9, as a negatively charged dye, adsorbs strongly on the surface decreasing the effective intrinsic positive charge of the P25 particles. The change of zeta-potential upon deposition of SiO₂ on P25 particles is expected to lead to a difference in the adsorption behavior of RhB – a positively charged dye. Upon deposition of SiO₂, the adsorption-desorption equilibrium of AB9 trends to negligible adsorption whereas for RhB, an increase of adsorption and thus decrease in concentration is observed for higher loadings. (Fig. 5.3b).

Figure 5.3: a) Zeta potential vs. SiO₂ loading (blue data points represent zeta potential in AB9 solution and red data points in RhB solution) b) Remaining concentration of AB9 (blue triangles) and RhB (red squares) after reaching the adsorption-desorption equilibrium. The initial concentration for AB9 and RhB was 16 mg/l and 12 mg/l, respectively.

Although negligible adsorption of AB9 on the surface of SiO₂ according to the results showing in Fig. 5.3b, we still can observe an improvement in the photocatalytic activity (2.5 times enhancement at 1.7 wt % Si). This demonstrates that eventual adsorption of reactants may play an insignificant role on the photocatalytic activity of SiO₂:TiO₂(P25).

Figure 5.4: Peak height of Si-OH signal in DRIFTS spectra for samples with various Si loading; Inset: DRIFTS spectrum of different loadings of SiO₂ on P25 in the characteristic range for surface OH groups.

Surface OH groups have been shown to have an important role on the photocatalytic activity of TiO₂.⁴¹ DRIFTS analysis provides insight into the quantity and type of

OH groups on the surface. The number of acidic surface OH groups on the SiO₂ surface (3740 cm⁻¹) increases with the Si loading reaching a plateau at 1.7 wt % Si. While for 0.4 wt % Si, the Ti-OH peaks (3600 – 3700 cm⁻¹) are still clearly visible, indicating only partial coverage of SiO₂ on P25, the Ti-OH peaks become less pronounced with increasing Si loading. These more acidic OH groups on the silica surface promote the generation of OH radicals.⁴² The trend in the number of OH groups strongly correlates with the improvement of the photocatalytic activity for low loadings until 1.7 wt% Si demonstrating the influence of OH groups on the photocatalytic activity. Moreover, the stagnant number of OH groups for higher Si loadings combined with the insulating properties would, therefore, result in the observed optimal loading for SiO₂ on TiO₂ for the photocatalytic degradation.

In order to check the reaction pathways scavenging agents can be utilized to block specific pathways to find which contribution dominates in the photocatalytic degradation. Organic pollutants are generally degraded via three pathways^{35, 43}: 1) direct oxidation by reaction with hole, and 2) decomposition by reaction with OH radicals, generated via h⁺_{VB}, or 3) using the excited e⁻ in the conduction band to facilitate the O₂ reduction followed by OH radical formation (Fig. 5.5b).

Figure 5.5: a) Kinetic constants for photocatalytic degradation of RhB or AB9 using DMSO (as CB electron scavenger and OH radical scavenger) or MeOH (as hole scavenger) for P25 and SiO₂:TiO₂(P25) (1.7 wt % Si). b) Schematic reaction pathways showing the influence of sacrificial agents DMSO and MeOH, dashed lines represent the reaction pathways that are prevented by the addition of sacrificial agents.

The addition of DMSO in large excess (scavenger/pollutant, mol/mol) to the suspension with P25, to ensure the prevalent reaction with the scavenger instead of the pollutant, surprisingly promotes the photocatalytic degradation of both AB9 and RhB. Even though DMSO used in photocatalytic studies is well known as OH radical scavenger^{9, 44-46}, these properties would only explain a decrease in the photocatalytic activity. Unfortunately, a detailed comparison of the experimental conditions with other

studies on P25 remains difficult due to the lack of information on the process conditions and scavenger concentration in many publications. However, other studies in the field of biology report DMSO as an acceptor for electrons to be reduced to dimethylsulfide.⁴⁷⁻⁴⁸ DMSO is, therefore, not only able to scavenge OH radicals but also might react with the CB electrons. In the case of P25, this would thus result in the observed increase in the photocatalytic activity since the scavenging of the CB electrons will lead to suppression of charge recombination, allowing more VB holes to react with the pollutant directly. The results lead to the conclusion that by adding DMSO, the degradation of the pollutant only can be achieved by direct oxidation. This also indicates that degradation via OH radicals is not very effective for P25. When adding MeOH – a hole scavenger⁴⁹ – in both cases (AB9 and RhB) for P25, the photocatalytic activity drops. In the case of RhB, the degradation is strongly hindered. This demonstrates, on the one hand, that MeOH blocks the degradation pathways via the VB but also that the degradation pathway via the CB is not a dominant pathway for dye degradation using P25. These results suggest that the primary contributing mechanism is direct oxidation of the pollutant, which advocates that the adsorption of pollutants is an essential step for the photocatalytic degradation using P25. For the degradation of AB9, MeOH decreases the activity only slightly. AB9 and MeOH are in competition for the adsorption on the surface because of the negative charge of AB9 which is attracted by the positively charged TiO₂ surface, which leads to the degradation of AB9 whereas RhB (with its positive charge, negligibly adsorbed on the TiO₂ surface) seems to remain unreacted. Although these results indicate that direct oxidation dominates the degradation pathway of dyes, the degradation of RhB suggests that direct oxidation is not the exclusive mechanism, but the generation of ROS (i.e. OH^{*}, O₂^{*}) is still a possible pathway, yet less pronounced.

In the case of SiO₂:TiO₂(P25), DMSO reduces the photocatalytic activity to a very low value. As stated earlier, DMSO blocks not only the degradation via OH radicals generated via the VB but also the CB pathways by scavenging the CB electrons. Therefore, only degradation via direct oxidation would still be accessible. However, very little activity is observed, which poses that direct oxidation is not very pronounced for dye degradation using SiO₂:TiO₂(P25). Adding MeOH decreases the activity to the same extent as DMSO. This implies that also CB pathways are not the predominant degradation pathways since the VB pathways are blocked for dye degradation. These findings suggest that the OH radicals generated via the VB pathway on the SiO₂ surface are the dominant species for dye degradation using SiO₂:TiO₂(P25). The OH radicals will be formed on the SiO₂ surface diffusing then into the solution.⁴²

SiO₂ layers are often used as anti-reflection layers, decreasing the scattered light from the coated particles.⁵⁰⁻⁵¹ However, this effect is, although present, in this case, not very pronounced according to the light absorption measurements (Fig. S5.4), due to the fact that the SiO₂ layer is ultrathin. The bandgap slightly shifts to larger values upon deposition of SiO₂ on the surface of P25 nanoparticles (Fig. S5.4), indicating that with higher Si loading negatively influences the light absorption. Previous research proposed that thin layers of SiO₂, despite the insulating properties of pure SiO₂, not

only allow the hole transfer to the surface by a tunneling effect due to a very thin coating of SiO_2 but also improve the charge separation due to the formation of a space charge layer as a consequence of Si-O-Ti interlinkages at the SiO_2 - TiO_2 interface.^{27, 52-53} The loading with low amounts of SiO_2 gives rise to incomplete coverage of the TiO_2 particles leaving the TiO_2 surface exposed to the environment. The excited electrons will, therefore, be able to react on the accessible TiO_2 surface facilitating a definitive charge separation.²² Overall, the efficient charge separation followed by electron consumption at the TiO_2 surface and simultaneous hole transfer to the SiO_2 surface inducing the subsequent reaction with the more acidic Si-OH groups will then result in the increased formation of OH radicals. However, not only is the activity increased, but also the mechanism has changed compared to P25, i.e. thin SiO_2 layers on TiO_2 change the contribution of the different pathways from direct oxidation (P25) to degradation via OH radicals (SiO_2 : TiO_2 (P25)).

Additionally, testing the photocatalytic behavior of both materials – P25 and SiO_2 : TiO_2 (P25) – by the simultaneous degradation of AB9 and RhB gives insight into the selectivity and degradation behavior towards these pollutants.

Figure 5.7: Simultaneous degradation of AB9 (blue squares) and RhB (red triangles) using a) P25 and b) SiO_2 : TiO_2 (P25) (1.7 wt % Si); c) first-order kinetic constants (0-20 min) for degradation of single compounds and simultaneous degradation of AB9 and RhB, the kinetic constants for simultaneous degradation are stacked

Table 5.1: Kinetic constants for the degradation of AB9, RhB (single), and RhB+AB9 (combined) using P25 and SiO₂:TiO₂(P25) (1.7 wt % Si). The kinetic constants were fitted from 0 to 20 min according to 1st order kinetics

Kinetic constant (min ⁻¹)	Acid Blue 9		Rhodamine B	
	Single	Combined	Single	Combined
P25	0.087 ± 0.001	0.079 ± 0.002	0.066 ± 0.001	0.009 ± 0.001
SiO ₂ :TiO ₂ (P25)	0.263 ± 0.006	0.046 ± 0.001	0.230 ± 0.003	0.154 ± 0.002

Following the color of the reaction solution by eye already gives a first indication for different degradation kinetics (Fig. 5.7a, b). While for P25, the red color (RhB) remains longer in solution, SiO₂:TiO₂(P25) maintains the blue color (AB9) for longer, indicating a quicker degradation of AB9 and RhB for P25 and SiO₂:TiO₂(P25), respectively. Moreover, SiO₂:TiO₂(P25) decolorizes the solution overall faster than uncoated P25, which proves the superiority of SiO₂:TiO₂(P25) over uncoated P25. In detail, P25 degrades AB9 faster than RhB showing first-order kinetics similar to the degradation of only AB9 in the solution (Fig. 5.7c, dark blue bars). On the other hand, the degradation of RhB is obstructed in the beginning when the concentration of AB9 is still high, only accelerating starting from 30 min when a low concentration of AB9 remains in the solution. This obstruction changes the kinetics of the degradation of RhB from 1st order kinetics, according to the Langmuir-Hinshelwood mechanism, over the whole range of reaction time, to two distinct time regimes, one which has limited adsorption due to the competition with AB9 (0-30 min) and the following (30-80 min), where the low AB9 concentration interferes less with the degradation of RhB. Noting that the direct dye oxidation is the dominant degradation mechanism, negatively charged AB9 adsorbed on the positive TiO₂ surface will impede RhB from getting access to reactive oxygen species and subsequently being degraded. Only after the concentration of AB9 on the surface has decreased sufficiently, RhB may reach the proximity of the TiO₂ to be attacked by radical species or ROS may be able to diffuse to the RhB molecules in solution additionally demonstrating the importance of adsorption on the surface advocating that the direct oxidation pathway is prevalent for P25. The similar speed of degradation for AB9 in the single degradation and combined degradation substantiates this pathway (Fig. 5.7c, Table 3.1).

For SiO₂:TiO₂(P25), in addition to faster degradation of RhB over AB9 in the dye mixture, the 1st order reaction mechanism remains valid for both individual dye degradations. With the positive charge, RhB prevails over AB9 for the competitive attraction to the negatively charged SiO₂ surface where the reactive oxygen species are formed, which explains the faster degradation of RhB (50 min) versus AB9 (70 min) as displayed in Figure 5.7b. In contrast to P25, both dyes are, however, degraded truly simultaneously in 1st order kinetics. Additionally, in all cases the degradation of the dye was complete since photocatalytic powder did not show any remaining coloring after

separation from the reaction solution. Comparing the kinetic constants with only a single dye in solution, the degradation proceeds overall slower, whereas the summation of the kinetic constants gives about equal values as for the individual degradation (Table 3.1). This indicates that both dyes are reached by degradation species simultaneously. This insight is in agreement with our previous finding that for $\text{SiO}_2:\text{TiO}_2(\text{P25})$, OH radicals are the predominant degradation pathway rather than direct oxidation on the surface. OH radicals – generated on the surface – can diffuse to a certain extent into the solution making the direct adsorption of the pollutant less relevant for the photocatalytic degradation. Considering this mechanism, the addition of both the individual kinetic constants for the combined degradation should add up to the kinetic constant obtained from the single dye degradation. However, the added kinetic constant is slightly lower than the kinetic constant of the single dyes. This behavior is already well observed in the literature that for higher pollutant concentrations, the kinetic constant decreases due to mass transport limitations.^{2, 35}

Figure 5.8: a) Scheme of the degradation of RhB, RhB + AB9, AB9 using P25 and $\text{SiO}_2:\text{TiO}_2(\text{P25})$, thickness of arrows represent the photocatalytic activity, pictures display the real samples taken after distinct time intervals; Photocatalytic mechanisms for b) P25 and c) $\text{SiO}_2:\text{TiO}_2(\text{P25})$ using no sacrificial agent, DMSO or MeOH; predominant reaction pathways are marked with thick arrows, pathways blocked by the sacrificial agent are displayed in dashed lines.

From the studies with sacrificial agents and the simultaneous degradation of two dyes, we can summarize that the P25 main, yet, not exclusive mechanism is direct oxidation for degrading organic pollutants, which can be concluded by the preferred degradation of the adsorbed pollutant. On the other hand, for SiO₂:TiO₂(P25), the simultaneous degradation of both dyes proves the preferred degradation via OH radicals, where direct contact with the surface is less important. OH radicals can diffuse to a certain extent into the solution to also oxidize molecules which are not directly adsorbed on the surface. Therefore, apart from the general improvement of SiO₂:TiO₂(P25) over P25 due to the easier OH radical generation from the Si–OH groups SiO₂:TiO₂(P25) degrades organic dyes less selectively. Although this lower selectivity might be disadvantageous for degradation of a defined effluent from a production site, the goal to clean water from an undefined water source requires unselective degradation of all organic matter to obtain good water quality. Clarifying the photocatalytic mechanism for SiO₂:TiO₂(P25) and applying this knowledge on the different degradation mechanisms opens doors to further developments where specific properties can be fine-tuned in catalyst development. Several modifications with different materials might, e.g., with atomic layer deposition, be able to improve individual pathways for radical generation and manufacture, therefore an overall better photocatalyst.

5

5.4. CONCLUSION

We have shown that thin layers of SiO₂ onto P25 can enhance the photocatalytic activity for the degradation of dyes independent on the charge of the pollutant. This indicates that the change of the surface charge by the deposition of SiO₂ layers on P25 only has little influence on the improved photocatalytic activity. The surface charge of SiO₂-coated TiO₂ (negative) versus uncoated TiO₂ (positive) changes only the preference of which pollutant will be degraded first when both are to be degraded simultaneously. But for independent dye degradation experiments, SiO₂:TiO₂(P25) shows superior photocatalytic activity, which can be ascribed to the more acidic OH groups on the surface introduced by the SiO₂ coating and the enhanced electron-hole separation due to the Ti–O–Si linkages at the TiO₂–SiO₂ interface as proposed in the literature. Using DMSO and MeOH as sacrificial agents, we have shown the difference in photocatalytic behavior of P25 and SiO₂:TiO₂(P25). From these experiments, it can be concluded that P25 prevalently degrades organic pollutants via direct oxidation by reaction with holes, whereas SiO₂:TiO₂(P25) mainly enhances the OH radical formation from reaction with holes, which is then responsible for pollutant degradation.

ALD designed multi-component photocatalyst Pt:SiO₂:TiO₂ (P25) particles with improved activity for pollutant degradation

6

Photocatalysts for water cleaning typically lack efficiency for practical applications. Here we present a bi-modified (Pt:SiO₂:TiO₂ (P25)) material that was developed using knowledge of working mechanisms of mono-modified catalysts combined with the abilities of Atomic Layer Deposition (ALD). The deposition of ultrathin SiO₂ layers on TiO₂ nanoparticles, applying ALD in a fluidized bed reactor, demonstrated in earlier studies their beneficial effects for the photocatalytic degradation of organic pollutants due to more acidic surface Si–OH groups which benefit the hydroxyl radical generation. Furthermore, our investigation on the role of Pt on TiO₂(P25) as an improved photocatalyst demonstrated that oxygen adsorbed on the Pt particles reacts to superoxide radicals as an important factor for the catalytic improvement. Having recognized that the two independent materials, SiO₂:TiO₂(P25) and Pt:TiO₂(P25), have different mechanisms improving the photocatalytic activity provided the opportunity to combine these two materials into a bi-modified material, where we deposited SiO₂ onto TiO₂(P25) followed by deposition of nanoclusters of Pt. The resulting Pt:SiO₂:TiO₂(P25) nanopowder exceeded the dye degradation performance of both the individual SiO₂:TiO₂(P25) (1.5 fold) and Pt:TiO₂(P25) (four-fold) catalysts by six-fold as compared to TiO₂ (P25). This approach shows that by understanding the individual materials' behavior and using ALD as an appropriate deposition technique, new materials can be designed, further improving the photocatalytic activity and moving one step closer to implementation. We demonstrate that ALD is an attractive technology to synthesize the catalysts developed by this approach in a precise and scalable way.

6.1. INTRODUCTION

Titania (TiO₂) was first discovered as an active photocatalyst almost half a century ago ¹ and still serves as a widely used benchmark for the development of new photocatalytic materials or as a substrate material to improve their photocatalytic properties. ²⁻⁴ The photocatalytic performance combined with affordable price, stability, and non-toxicity are a few reasons for this success in scientific publications. However, its implementation in real applications, despite these advantages, is hampered by poor sunlight utilization, due to a large bandgap, and charge recombination resulting in insufficient efficiency. ⁵⁻⁷ Improving TiO₂ by incorporating several elements into the lattice (bulk modification) or depositing different materials onto the surface (surface modification) has been extensively explored ever since. ⁸⁻¹³ This includes modifications with both noble metals and metal oxide for the improvement in: 1) reactant adsorption and reactivity by surface modification, 2) light absorption by bandgap modification, 3) charge utilization by modification of the band levels. These three approaches are dominantly targeted to develop a better catalyst. On the other hand, especially improvements in the rates and mechanisms of radical generation are often underestimated since they are often attributed to the improved light absorption or reduced charge recombination. However, it has been shown that surface modifications, which lead to a different type and amount of terminal OH groups, result in an increased OH radical generation. ¹⁴ Factors such as adsorption of the reactants for the ROS formation have been demonstrated to play a crucial role in the enhancement of the photocatalytic activity. ¹⁵⁻¹⁷ Overall, the photocatalytic mechanism gives four different points to tackle for making improved materials: ¹⁸⁻¹⁹

- 1) Adsorption of reactants
- 2) Creation of charge carriers by light absorption
- 3) Charge carrier separation
- 4) Degradation reactions, along:
 - a) Conduction band pathway via superoxide radicals (converting into hydroxyl radicals)
 - b) Valence band pathway via direct oxidation
 - c) Valence band pathway via hydroxyl radicals

While earlier material development focused more on the enhancement using single modifications on active materials, recently, multicomponent systems have received more attention. ²⁰⁻²⁵ However, most works on multicomponent materials focus on combining materials where components improve the processability of the catalyst for their implementation in future reactors (i.e., dispersion, separation using magnets). ^{21, 26} Multicomponent materials containing iron oxide as a core material, due to its magnetic properties, are good examples of materials improving both the processability and activity of a catalyst to enhance separation from the liquid after the reaction. ^{21, 24} Another approach is to modify the surface of an already photocatalytic material with a coating to change the deposition properties of the subsequently added co-catalyst i.e., increasing control of the particle size by modifying the surface or

preventing the agglomeration of deposited nanoclusters of the surface by a cover layer.²⁷⁻³⁰ However, the manipulation of physical properties such as increased surface area, the addition of magnetic properties, or a beneficial layer to improve the dispersion of co-catalyst particles³¹⁻³² is more straightforward than modifying the photocatalytic mechanisms themselves. The question arises whether multiple components, each enhancing the photocatalytic process, can be combined to reach higher enhancement than each component individually.

The approach of combining materials to make a more complex and improved structure can be tackled utilizing the advantages of atomic layer deposition. This technology allows to precisely control the deposition of various materials onto a surface. The advantages of confined scalable bottom-up building up of multicomponent catalyst materials could lead to the development of improved photocatalysts. However, building up multicomponent catalysts requires detailed knowledge of the photocatalytic working principles of the base materials as well as the building blocks and their interaction.

Surface deposited Pt on TiO₂ (P25) is a well-developed catalyst and has shown superior activity for the photocatalytic degradation of various organic pollutants.³³⁻³⁴ Pt enhances the photocatalytic activity of TiO₂(P25) for dye degradation by acting as an adsorption surface for O₂ suppressing charge carrier recombination by facilitating improved radical generation via the conduction pathway in the presence of dissolved O₂.^{15, 35} Our previous findings for the role of an ultrathin SiO₂ coating on TiO₂(P25) nanoparticles demonstrated an improved photocatalytic activity due to the improved generation of OH radicals at the SiO₂ surface from the more efficiently separated holes on the SiO₂ surface by the more acidic Si-OH surface groups^{14, 17}, which is different from TiO₂(P25) as well as Pt:TiO₂(P25). From this detailed analysis of the photocatalytic mechanisms, the question arises whether the advantages of these bi-material composites, Pt:TiO₂(P25) and SiO₂:TiO₂(P25), can be combined in a tri-material composite resulting in a further improved photocatalyst for dye degradation. Here, we demonstrate that catalyst development following the design principles of combining characteristics that are improving individual aspects of the photocatalytic reaction pathways can lead to superior photocatalysts by taking advantage of the controllability of the deposition using ALD.

6.2. EXPERIMENTAL SECTION

6.2.1. Synthesis

TiO₂ nanoparticles (P25, mean diameter ~21 nm, specific surface area of ~54 m² g⁻¹ measured by BET) was purchased from Evonik Industries (Hanau, Germany). Silicon tetrachloride (SiCl₄) and trimethyl(methylcyclopentadienyl)platinum(IV) (MeCpPtMe₃) were purchased from AlfaAesar (Karlsruhe, Germany) and Strem Chemicals (Bischheim, France), respectively. Both chemicals were stored in a stainless steel

bubbler for mounting into the ALD setup. Acid Blue 9 (Brilliant Blue FCF) and sodium polyphosphate were purchased from SigmaAldrich (Zwijndrecht, The Netherlands) and used without further purification. Pt:SiO₂:TiO₂(P25) was synthesized via a two-step deposition process:

1) SiO₂ was deposited on TiO₂(P25) on a homebuilt ALD setup in a fluidized bed under atmospheric pressure, as described in detail elsewhere.³⁶⁻³⁷ In brief, 5 g of the TiO₂(P25) powder was put in a quartz glass column (diameter 26 mm, height 500 mm), which was then placed on a vertical vibration table (Paja 40/40-24, Oosterhout, The Netherlands) to assist fluidization. The powder was sieved prior to the ALD experiments with a mesh size of 250 μm to break or exclude larger agglomerates. SiO₂ layers were deposited using SiCl₄ and H₂O as precursors, which were both kept at room temperature in stainless steel bubblers. The reactor was heated to 100 °C throughout the deposition process using an IR lamp. For different SiO₂ loadings, up to 40 cycles were applied using an exposure time of 30 s SiCl₄ and a 3 min H₂O pulse. Purging steps of nitrogen for 3 min and 8 min, respectively, separated the precursor pulses.

2) The SiO₂:TiO₂(P25) powder was split into 1.5 g batches, which were then used for the deposition of Pt clusters on the SiO₂:TiO₂(P25) surface using MeCpPtMe₃ and O₂ as precursors. The Pt precursor was stored in stainless steel bubblers and held at 70 °C. For those experiments, one ALD cycle was performed using exposure times for the Pt precursor ranging from 20 sec to 5 min. The O₂ exposure was set to 5 min, and both precursor exposures were separated using purge steps of 5 min with N₂, respectively. Afterward the coated powders were treated under an atmosphere of 5 % H₂ in N₂ (v/v) in a fixed bed reactor. The temperature was ramped up from room temperature to 200 °C with a rate of 2 °C/min and then was held constant for 5 min after which the powder was allowed to cool to room temperature.

6.2.2. Characterization

For the ICP-OES analysis, approximately 30 mg of sample was digested in a mixture of 4.5 mL 30% HCl, 1.5 mL 65% HNO₃, and 0.2 mL 40% HF using a microwave for 60 min. After the digestion, the samples were diluted to 50 mL with MilliQ water, and the weight percentage (wt. %) of Pt, Si, and Ti were analyzed with a Perkin Elmer ICP-OES 5300DV (Waltham, MA, USA) system. The samples were also diluted 20 times for the analysis of the Ti concentration.

TEM micrographs were acquired from a JEOL JEM1400 transmission electron microscope (Akishima, Japan) at 120 kV. As-deposited Pt:SiO₂:TiO₂(P25) nanoparticles were suspended in ethanol and transferred to Cu transmission electron microscopy grids (3.05 mm in diameter, Quantifoil, Großlöbichau, Germany).

X-ray photoelectron spectra (XPS) were recorded on a ThermoFisher K-Alpha (Blijswik, The Netherlands) system using Al K α radiation with a photon energy of 1486.7 eV. A sufficient amount of powders was immobilized on copper tape before loading into the XPS chamber. Survey scans were acquired using a 400 μm spot size, 55 eV pass energy, and 0.1 eV/step with charge neutralization. The peak positions were calibrated by referencing the C 1s peak to 284.8 eV and previous background subtraction using the Thermo Advantage software (v5.985, accessed on 19 Feb 2019).

6.2.3. Photocatalytic testing

The photocatalytic activity was evaluated in a 100 ml glass bottle (irradiation surface 11.3 cm²) with a 30 ml solution of Acid Blue 9 (16 mg/l in deionized water) and 30 mg of catalyst powder. Sodium polyphosphate (0.3 ml, 100 g/l in water) was added to aid the dispersion of the powder.³⁸ The powder was dispersed by sonicating the solution with the powder for 10 min. Additionally, the dispersion was stirred in the dark for another 20 min in order to reach the dye-adsorption-desorption equilibrium. The test was executed in open air in an Atlas SunTest XXL solar simulator equipped with three Xenon lamps (45 W/m²)³⁹ to ensure homogeneous light distribution simulating the sun's spectrum in both the UV and visible light range. Multiple samples were irradiated on a multiple stirring plate (700 rpm). Samples of 1 ml were taken after distinct times of irradiation, were then centrifuged, and the dye concentration in the supernatant liquid was determined using a UV/Vis spectrometer (Hach-Lange DR5000). The absorption was measured at 629 nm, which represents the maximum absorption for Acid Blue 9. According to 1st order kinetics, $\ln(C_0/C_t)$ was plotted vs. time, and the slope of the linear regression represents the kinetic constant.

6.3. RESULTS & DISCUSSION

Previously, we have reported on the mechanisms of SiO₂:TiO₂(P25)¹⁶⁻¹⁷ and Pt:TiO₂(P25)³⁵ for the photocatalytic degradation of organic pollutants. With an optimum loading of 1.7 wt. % Si we concluded that for TiO₂ (P25), a very thin SiO₂ layer combined improve charge separation with an increased OH radical formation due to more acidic surface OH groups at the SiO₂ surface leading to a higher degradation rate of organic pollutants in water. Too thick an SiO₂ layer shields off the TiO₂ and drastically reduces the photocatalytic activity. For Pt:TiO₂(P25), the role of dissolved O₂ in combination with the enhanced charge separation turned out to be crucial for the enhancement of the photocatalytic activity. Pt acts as a recombination center and reduces the photocatalytic activity if the electrons cannot be harvested adequately in case no O₂ is present or the Pt loading is too high. This gave rise to the improved behavior for Pt:TiO₂(P25) samples with an optimal Pt loading of 0.34 wt. %. Higher loadings decreased the photocatalytic activity even to lower values than intrinsic

TiO₂(P25) (>2 wt % Pt). In earlier research, SiO₂ layers often have been used to encapsulate Pt nanoclusters on the surface of TiO₂ to improve the Pt nanoparticle dispersion by preventing noble metal cluster agglomeration, improving the catalytic performance.^{31-32, 40} According to our previous results, it would be more advantageous to keep Pt clusters exposed on the surface by the deposition of SiO₂ followed by Pt, since both materials, Pt and SiO₂, are crucial for the generation of radicals on the surface. The overcoating of Pt with SiO₂ would reduce the effect of Pt adsorbing O₂ and possibly even give a worse photocatalyst due to the charge recombination property of the Pt nanoclusters in case the lack of access to O₂ prevents the harvest of electrons. Therefore, for the material design, we chose to coat first the TiO₂ (P25) nanoparticles with SiO₂ and subsequently deposit Pt onto the SiO₂:TiO₂(P25) substrate (Figure 6.1a). Despite the spatial separation of the Pt clusters from TiO₂, electrons may still be able to transfer to the Pt clusters as for the SiO₂:TiO₂(P25) catalyst excited electrons may still reach through the ultrathin SiO₂ layer to be harvested.¹⁶⁻¹⁷ For low Si loadings the layer may be porous and incomplete which would also give the chance for a reaction of the electrons directly on the TiO₂ surface. By applying 2 to 40 ALD cycles of SiCl₄ and H₂O the loading evolved from 0.4 to 2.7 wt % Si in a conformal manner (Figure 6.1a). Afterward, Pt was deposited onto SiO₂:TiO₂(P25) in various loadings by using different pulse times (20 s to 5 min) for MeCpPtMe₃ and O₂ as a counter reactant (Figure 6.1b). In order to reach the required very low Pt loadings the pulse time was in the undersaturation regime resulting in a dependency of the pulse time versus Pt loading rather the commonly used cycle number. Using this approach, we could precisely tune the loadings for both the SiO₂ coating and the Pt clusters.

Figure 6.1: a) Development of the Si loading with the number of applied SiO₂ ALD cycles on bare TiO₂ (P25) particles, b) Development of the Pt loading with the Pt precursor pulse time (MeCpPtMe₃) on SiO₂ overcoated TiO₂ (P25) particles (2.1 ± 0.2 wt. % Si).

This design of experiments gives a matrix of various combinations of SiO₂ and Pt loadings onto P25 nanoparticles. Analyzing the morphology with TEM revealed the growth of SiO₂ as conformal sub-nanometer layers layers with various loading (Figure 6.2a) onto P25 and the Pt clusters (1–2 nm) deposited onto the SiO₂ layers in the second step (Figure 6.2b, Figure 6.S1). This is in agreement with our previous studies that show the growth of layers of SiO₂ due to the high affinity towards the TiO₂ surface.¹⁶ On the other hand, the high surface energy of Pt results in the expected island growth on the surface of SiO₂, resulting in similar behavior as the deposition of Pt clusters on P25 itself.⁴¹ Due to the very minute addition of material on the P25 particles TEM pictures confirms an unchanged particle size of Pt:SiO₂:TiO₂(P25) particles compared to pristine P25 of about 30 nm (Figure 6.2b). For lower loaded SiO₂ samples, the layers are not clearly visible due to resolution limitations of the TEM. It is expected that for a low number of cycles, the SiO₂ layer may be incomplete, and the TiO₂ surface is still exposed. XPS confirmed the deposition of both materials, SiO₂ and Pt (Figure 6.2c–e). From the high-resolution spectra, we can identify the characteristic peaks for each element – Ti, Si, and Pt. For the range between 450 eV and 475 eV, the characteristic Ti(IV) peaks for TiO₂ can be observed at binding energies of 458.68 eV (Ti 2p_{3/2}) and 464.34 eV (Ti 2p_{1/2}). The Si 2p peak characteristic for SiO₂ arises at 102.36 eV. After deconvolution of the Pt HR-XPS spectrum, three peaks arise where the peaks at 70.90 eV and 74.01 eV can be fitted to Pt(0) 4f_{7/2} and Pt(0) 4f_{5/2} respectively correlating them to the metallic Pt species, and at a binding energy of 76.06 eV, a satellite peak from the Ti 3s peak arises. XRD studies on TiO₂(P25) after modification with SiO₂ and Pt using ALD showed no change in the TiO₂ crystal structure featuring anatase and rutile phase typical for the mixed phase P25 nanoparticles (Figure S6.3). The modified TiO₂ (P25) showed a peak at 46.6° indicating the Pt(200) facet. However, other facets of Pt were not observable. Due to the only minute changes, i.e., ultra-thin layers of SiO₂ on the surface of TiO₂ XRD features of SiO₂ remain undetected. UV/Vis absorbance spectra (measured with DRS) show that the addition of neither SiO₂ layers nor Pt clusters leads to a significant change in the bandgap of the modified catalysts (Figure S6.4). The deposition of Pt clusters leads (for both TiO₂(P25) itself as well as SiO₂:TiO₂(P25)) to strong absorption throughout the visible spectrum caused by the metallic particles on the surface of the catalysts. Previous studies on the effect of the BET surface area of the single modified materials SiO₂:TiO₂(P25) (54 m²/g)¹⁶ and Pt:TiO₂(P25) (55 m²/g)³⁵ demonstrated that a minute additions of SiO₂ and Pt are not significantly affecting the BET surface area compared to pure TiO₂ (P25) (55 m²/g). Therefore we expect a similar BET surface area for the bi-modified Pt:SiO₂:TiO₂(P25) photocatalyst. Furthermore, the adsorption of Acid Blue 9 on the surface of the prepared catalysts after reaching the adsorption-desorption equilibrium did not change significantly upon modification of TiO₂(P25) (Figure S6.5)

Figure 6.2: a) Deposition scheme for the material development of Pt:SiO₂:TiO₂(P25), b) TEM picture of Pt:SiO₂:TiO₂(P25) (1 wt. % Si, 1.23 wt. % Pt), grey large particle are TiO₂(P25) particles, SiO₂ layer around TiO₂(P25) particles can be observed, dark spots indicate Pt nanoclusters, c) Ti HRXPS spectrum with typical TiO₂ features, d) Si HRXPS spectrum, single peak represents SiO₂ (orange), e) Pt HRXPS spectrum, doublet peak represents Pt metal (brown), single peak represents Ti satellite peak (green).

In order to investigate the photocatalytic performance of the combined material (Pt:SiO₂:TiO₂(P25)), it is compared to the original material (TiO₂(P25)) and the single-modified materials – Pt:TiO₂(P25) and SiO₂:TiO₂(P25). First, the photocatalytic degradation for those individual compounds is investigated to benchmark the measurements. As compared to TiO₂(P25), the optimal Pt loading of about 0.34 wt. % gives a 4-fold increase in the activity of Pt:TiO₂(P25) for the photocatalytic degradation of AB9 (Figure 6.3a) while SiO₂:TiO₂(P25) shows a 1.5-fold increased photocatalytic activity with an optimal loading of about 1.2 wt. % Si (Figure 6.3b). In our previous research, an optimal loading of about 1.8 wt. % Si was reported, which is in line with the results in this paper.¹⁷

In Figure 6.3, we show the photocatalytic degradation of Acid Blue 9 for different coated Pt:SiO₂:TiO₂(P25) samples with various SiO₂ and Pt loading in order to find the optimum loading. We can identify an optimal behavior in the range of 1.5–2.2 wt. % Si and around 0.3 - 0.4 wt. % Pt (Figure 6.3c). This range is also covering the ranges of individual catalysts SiO₂:TiO₂(P25) and Pt:TiO₂(P25) perform in an optimal way. The best performing catalyst of the Pt:SiO₂:TiO₂(P25) series (1.9 wt. % Si, 0.60 wt. % Pt) degrades AB9 about six times better than P25. Evidently, the combination of Pt nanoparticles onto sub-nanometer layers of SiO₂ coated on P25 particles results in an improved photocatalytic material. Although the best performing catalyst with 0.60 wt. % Pt is slightly outside the range of the optimal loading (Table 6.1, Figure S6.2) for Pt:TiO₂(P25) mono-modified (0.34 wt. %), the fitting of the data (2D polynomial model) reveals that the optimal loading for the mono-modified materials Pt:TiO₂(P25) and SiO₂:TiO₂(P25) coincides with the optimal loadings for these mono-modified catalysts. This indicates that there is limited interaction between the improvement mechanisms of depositing SiO₂ and Pt onto P25. In this context it may be speculated that the growth of Pt on the SiO₂ coating may positively influence particle

size distribution due to a change in surface energy. However, a study on the detailed evolution of the particle size distribution of Pt clusters on different surfaces would be outside of the scope of this study yet important for further research.

On the one hand, a sub-nanometer SiO_2 layer on TiO_2 (P25) particles improves the OH radical generation at the SiO_2 surface from the holes generated in the VB. On the other hand, Pt clusters facilitate effective electron-hole-pair separation by using the TiO_2 CB electrons as reducing agents to generate superoxide radicals ($\text{O}_2^{\cdot-}$) from dissolved O_2 . Combining both materials, SiO_2 and Pt, with TiO_2 (P25) increases the photocatalytic activity by increasing mainly the radical generation.

Figure 6.3: Kinetic constant for degradation of AB9 a) with different loadings of Pt on TiO_2 (P25), b) with different loadings of SiO_2 on TiO_2 (P25), c) combined Pt: SiO_2 : TiO_2 (P25) material with different loadings of Pt and SiO_2 for the degradation of AB9 (fitted)

Table 6.1: Kinetic constants for the best performing photocatalysts for the mono-modified and bi-modified TiO₂-catalysts. Kinetic constants are calculated from pseudo 1st order kinetics.

	TiO ₂ (P25)	Pt:TiO ₂ (P25)	SiO ₂ :TiO ₂ (P25)	Pt:SiO ₂ :TiO ₂ (P25)
Optimal loading	-	0.34 wt. % (Pt)	1.2 wt. % (Si)	0.6 wt. % (Pt), 1.9 wt. % (Si)
Kinetic constant (min⁻¹)	0.044	0.169	0.065	0.267
Improvement ratio	1	3.84	1.48	6.07

The current study does not show any serious deactivation of the photocatalyst during the use of the photocatalyst. Nevertheless, a detailed analysis of the long-term reusability will be required for the implementation in future reactors for water treatment and is recommended to be subject to follow-up research. Applying the same strategy followed in this research to improve the photocatalytic activity using a base material with increased light absorption could further increase the overall performance. For example, N-doping has been shown to reduce the bandgap of titania, increasing the light absorption in the visible light regime.⁴²⁻⁴³ Adding another material on the surface is, on the other hand, not recommended. This would probably lead to coverage of the photocatalytic relevant surface groups reducing the reactive oxygen species generation. Furthermore, the modification of TiO₂ by layer/nanocluster combination using cheaper materials as replacement for e.g., Pt may result in both efficient and cheaper catalysts. In our experiments we were able to coat powder of up to 5 g (~270 m² surface area) using atomic layer deposition in a fluidized bed. This technique provides therefore a great opportunity to scale up the preparation of multicomponent catalysts.

6.4. CONCLUSION

This work shows that by the smart combination of different materials onto TiO₂(P25), better photocatalyst can be engineered using the excellent precision of ALD in a fluidized bed. As a successful example we designed a Pt:SiO₂:TiO₂(P25) material with improved photocatalytic properties by depositing Pt clusters on SiO₂ coated TiO₂(P25). The choice of the coating materials Pt and SiO₂ was based on our previous detailed analysis of the photocatalytic mechanism of both SiO₂:TiO₂(P25) and Pt:TiO₂(P25). ALD provided the opportunity to precisely control the loading of SiO₂ and Pt, resulting in a matrix of various loaded Pt:SiO₂:TiO₂(P25) surface modified nanoparticles. We showed that this material accelerates the photocatalytic degradation rate of Acid Blue 9 by a factor 6, which is superior to both SiO₂:TiO₂(P25) (1.5×) and Pt:TiO₂(P25) (4×).

Thermal Atomic Layer Deposition of Gold Nanoparticles: Controlled Growth and Size Selection for Photocatalysis

7

Gold nanoparticles have been extensively studied for their applications in catalysis. For Au nanoparticles to be catalytically active, controlling the particle size is crucial. Here we present a low temperature (105 °C) thermal atomic layer deposition approach for depositing gold nanoparticles on TiO₂ with controlled size and loading using trimethylphosphino-trimethylgold (III) and two co-reactants (ozone and water) in a fluidized bed reactor. We show that the exposure time of the precursors is a variable that can be used to decouple the Au particle size from the Au loading. Longer exposures of ozone narrow the particle size distribution while longer exposures of water broaden it. By studying the photocatalytic activity of Au/TiO₂ nanocomposites we show how the ability to control particle size and loading independently can be used not only to enhance performance but also to investigate structure-property relationships. This study provides insights into the mechanism underlying formation and evolution of Au nanoparticles via a vapor phase technique, which eliminates the shortcomings of conventional liquid-base processes.

7.1. INTRODUCTION

Gold was long thought to be far less catalytically active than other transition metals. Yet studies in the late 80s showed that Au nanoparticles supported on metal oxides such as TiO₂ exhibits an extraordinary high activity towards various catalytic oxidation and reduction reactions, such as low-temperature combustion, partial oxidation of hydrocarbons, hydrogenation of unsaturated hydrocarbons, and reduction of nitrogen oxides.¹⁻¹⁰ The catalytic properties of Au nanoparticles originate from quantum, electronic, and geometric finite-size effects, and are therefore strongly related to the particle size.¹⁰⁻¹¹ For example, Au nanoparticles supported on TiO₂ exhibit a high activity towards the oxidation of CO only when their size is within an optimal range of 2-3 nm¹⁰. Furthermore, Au nanoparticles can extend the absorption of TiO₂ in the visible range to an extent that depends on their size thanks to plasmon resonance, that is, the resonant oscillation of free electrons induced by incident light.¹²⁻¹³ While the sensitivity of the structure-property relationship of Au nanoparticles can add a new dimension to the design of catalysts, it also poses a challenge. This is because practical applications often require large amounts of material, and fabricating supported nanoparticles with a controlled size in a scalable fashion remains challenging.¹⁴⁻¹⁶

Conventional techniques for the synthesis of supported Au nanoparticles typically rely on liquid-phase processes.¹⁷⁻¹⁹ However, the practical applicability of these methods is limited by a number of shortcomings: high levels of impurities in the final product arising from residual solvents, poor control over the composition and the size distribution in large batches, and high sensitivity to operating conditions.²⁰ These factors can significantly affect the lifetime, activity, selectivity, and stability of the catalyst.^{15, 21} Thus, an alternative solvent-free, controllable, and scalable method is highly desired.

Atomic layer deposition (ALD) is a vapor-phase deposition technique that is emerging as a promising method for the synthesis of supported nanoparticles as it boasts high precursor utilization efficiency, low degree of contamination of the final product, and an excellent degree of control over both the metal loading and the particle size.^{16, 22-28} While there exist over seventy ALD processes for the deposition of noble metals, only limited success with regards to Au has been reported.¹ Two successful studies on ALD of Au include a plasma process at 120 °C using (trimethylphosphino)-trimethylgold(III) as metal precursor; and a thermal process at 180 °C, with dimethylgold(III)(diethylthiocarbamate) as metal precursor.²⁹⁻³⁰ In both studies, the deposition was carried out on flat substrates under vacuum conditions. While such processes are certainly promising for a number of applications, plasma and vacuum processes are not readily scalable to large quantities of high-surface-area supports, which are relevant for catalytic applications.¹⁶

In this work, we demonstrate a synthesis method for scalable fabrication of supported Au nanoparticles on TiO₂ via thermal atmospheric-pressure ALD. This ALD process

uses trimethylphosphino-trimethyl gold (III) as the metal precursor, and ozone and water as counter reactants, at low temperatures (105 °C). We show that it is possible to control the broadness of the particle size distribution while retaining a given metal loading by tuning the exposure of the counter reactants. Interestingly, ozone and water have opposing effects on the size distribution: long ozone exposures narrow the size distribution, whereas long water exposures broaden it. Finally, by leveraging our independent control over loading and particle size, we explore the structure sensitivity of the Au/TiO₂ nanocomposites against the photocatalytic decomposition of a model dye. In doing so, we show a threefold enhancement in the photocatalytic activity of commercial titania P25. By boasting an independent control over particle size and metal loading, our thermal atmospheric-pressure ALD process can open new possibilities for the application of supported Au nanoparticle in large scale catalytic processes.

7.2. EXPERIMENTAL SECTION

7.2.1. Material Deposition

Aeroxide P25 titanium oxide particles from Evonik industries with a mean diameter of 32.7 nm, a specific area of 52.4 m²/g were used as the support material for the deposition of Au. The nanoparticles were treated with oxygen (99.999 vol%) for 10 min followed by nitrogen (99.999 vol%) for 10 min at 105 °C before the Au ALD experiments. The deposition experiments were carried out in a custom-built vibration-assisted fluidized bed ALD reactor operating at atmospheric pressure described elsewhere.³¹ The ALD reaction chamber was a 25 mm I.D. glass column into which 2 g of titania P25 NPs were loaded for each ALD run. The metal precursor bubbler and the line connecting the bubbler to the reactor were heated to 85 °C and 95 °C, respectively. An infra-red lamp was used to heat and maintain the reactor at 105 °C. Trimethylphosphino-trimethyl gold (III) was synthesized as described previously.²⁹

7.2.2. Materials Characterization

To determine Au and P loading (wt%) on powders, Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES) analyses were performed in Perkin-Elmer Optima 5300DV Optical emission spectrometer. About 25 to 50 mg of samples were used for each ICP-OES measurement.

X-ray Photoelectron Spectroscopy (XPS) samples were analyzed in a Thermo Scientific K-Alpha X-ray spectrometer. The X-ray source was a monochromatic AlK α source with a beam energy of 1486.7 eV and a spot size of 400 μ m. The obtained Au 4f, P 2p, O 1s, C 1s, and Ti 2p spectra were processed in CasaXPS.

Diffuse Reflectance Infrared Fourier-Transform Spectroscopy (DRIFTS) measurements were made using a NICOLET 8700 spectrometer in diffuse reflectance mode with a range of 500–4000 cm^{-1} (128 scans).

For Transmission Electron Microscopy (TEM) measurements, the NPs were suspended in a droplet of ethanol, which was then cast on a copper TEM grid. The TEM micrographs were obtained by a JEOL JEM 1400TEM operating at 120 kV. Number based particle size distributions were obtained from image analysis of the micrographs. The projected area of each particle (A_{p_i}) was measured manually using ImageJ. Then the equivalent particle diameter was estimated as $d_{p_i} = \sqrt{4A_{p_i}/\pi}$ for ~100–600 NPs from 15 to 40 micrographs taken at different locations of the TEM grid and at different magnifications. The measured diameters are displayed as binned scatter plots and box-and-whisker diagrams. In the scatter plots, all the measured diameters are grouped into bins whose width and height indicate different size ranges and their relative frequency, respectively. The box-and-whisker diagrams represent different statistical descriptors of the populations: the whiskers indicate the minimum and maximum observed diameter, the lower and upper side of the box indicate the first to the third quartile of the population, respectively, and the diamond inside the box indicates the mean diameter.

Diffuse Reflectance-Ultraviolet/Visible Spectroscopy (DRS) measurements were performed on a Perkin-Elmer Lambda 900 spectrometer in diffuse reflectance mode at a range of 250 to 800 nm using an integration sphere. Barium sulfate (BaSO_4) was used as a blank standard.

The photocatalytic tests were performed on organic Rhodamine B dye. First, 30 mg of catalyst material was dispersed into a solution of Rhodamine B (30 ml, 16 mg/l, in DI water). Then Sodium polyphosphate (0.33 ml, 100 g/l in DI water) was added to improve the dispersion of the particles. The dispersion was sonicated for 10 min and stirred in the dark for 20 min to reach the adsorption-desorption equilibrium. Then the samples were top-illuminated in an Atlas SUNTEST XXL equipped with three Xenon lights to ensure homogeneous light distribution (45 W/m^2) simulating the sun's spectrum in both the UV and visible light range.³² The reactor (irradiation surface 11.3 cm^2) was cooled using a water bath at $20 \text{ }^\circ\text{C}$ while the dispersion was continuously stirred during the test using a magnetic stirrer at 700 rpm. After distinct time intervals, samples of 1 ml were taken, centrifuged, and the light absorption at 629 nm was measured using a HACH LANGE DR5000 UV/Vis Spectrometer to follow the degradation of Rhodamine B by time. The kinetic constant was calculated using the 1st order kinetics.

7.3. RESULTS AND DISCUSSION

As described by Griffiths et al., trimethylphosphino-trimethyl gold(III) vapor pressure follows a Antoine equation ($\ln(p) = 0.059T - 1.65$). For titania nanoparticles with the surface area of $50 \text{ cm}^2/\text{g}$, a long Au dosage time (+60 min) is required to saturate the titania surface groups. Thus for demonstrating the saturation behavior of this precursor, we only perform 1 ALD cycle. To achieve the thermal ALD of Au on gram-scale batches of high-surface-area powders, we adapted the plasma process reported by Griffiths et al., which consists of ABC cycles comprising the sequence of pulses: Au precursor/oxygen plasma/water. In our process, the oxygen plasma step is replaced by exposure to 1 bar of ozone. The effect of the exposure to ozone and water is studied by performing more cycles (3 to 9) where short exposures of the Au precursor were used. As we will discuss below, within the cycle range explored here (1-9), the deposition process results in the formation of nanoparticles rather than films. In particular, we show that both the Au loading and the size distribution of the nanoparticles can be controlled even when running the chemisorption of the Au precursor in a sub-saturation regime.

Figure 7.1: Self-limiting behavior of the Au precursor chemisorption. (a) Evolution of the Au loading on TiO₂ nanoparticles after one cycle with increasing exposure time. The ozone and water exposure times were: 10 min and 30 secs, respectively, and the reactor temperature was kept at 105 °C (The dashed red line is drawn to guide the eye). (b) FTIR spectra acquired at 120 °C on the Au/TiO₂ nanocomposites obtained after 1 ALD cycle with different Au precursor exposure times.

The self-limiting behavior of the precursor chemisorption was probed by measuring the Au loading (wt%) on the TiO₂ nanopowders after exposure times in the range of 5-150 min. The Au loading was measured with ICP-OES (Fig 7.1a). For all saturation experiments, ozone and water exposures were kept at 10 min and 30 secs, respectively. The Au loading progressively increases up to exposure times of about 60 min, after which it plateaus and remains virtually constant at around 2.7 wt% within a time window of about one hour, i.e. for a total exposure of 120 min. This demonstrates the self-limiting nature of the deposition process. Upon prolonging the exposure time up to 150 min, well past the minimum saturation time, higher Au loadings were observed (Supporting info Fig 7.1). At such long exposures, it is not surprising that parasitic Chemical vapor deposition (CVD) components might manifest themselves. In fact, although precursor is known to decompose at about 120 °C and the bulk temperature of the reactor is kept constant at 105 °C, after the surface reactions have terminated unreacted precursor can still be expected to decompose at a very slow rate, which over long time scales (~30 min) can add up to noticeable amounts of precursor being decomposed. Furthermore, local hot spots occurring sporadically across the reactors can also contribute to a small CVD component. Nonetheless, a self-limiting deposition is retained over a broad time window (~1 hour), attesting the robustness of this ALD process. Furthermore, a loading of 2.7 wt% after one cycle corresponds to a growth per cycle of ~1.6 Au atoms/nm² and thus to ~0.1 Au(111) monolayer (1.387 × 10¹⁵ atoms/cm²).³³ The deposition of less than a monolayer per cycle further attests to the ALD-nature of the precursor chemisorption on TiO₂.³⁴

A detailed analysis of the TiO₂ surface functional groups by FTIR measurements reveals an interesting trend in the evolution of surface functional groups. Upon longer Au precursor exposures, the Ti-OH peak decreases while a -CH peak emerges. Furthermore, the H-O-H bending peak related to adsorbed water also decreases with an increase in the Au precursor exposure (Fig 7.1b).

To gain further insights into the growth process, we repeated the saturation experiments by performing 5 ALD cycles. This allowed us to study the aggregation of the as-deposited Au atoms into nanoparticles in more detail, as lower cycle numbers result in nanoparticles too small to be observed with TEM. In particular, we studied the evolution of the loading and the size distribution of the nanoparticles by exposing the TiO₂ nanopowders to the Au precursor for pulse times in the range of 5-40 min (i.e., sub-saturating doses). Similar to the saturation experiments, we kept the ozone and water exposures at 10 min and 30 sec, respectively (Fig 7.2).

Image analysis of TEM micrographs together with elemental analysis shows that an increase in Au loading with increasing Au precursor exposure time is accompanied by a higher degree of metal aggregation, as attested by the increase in particle size, the broadening of the size distribution, and the decreased number of particles (Fig 7.2). This points to the fact that sintering mechanisms, such as nanoparticle diffusion and coalescence or Ostwald ripening, play an important role during the growth process.^{22, 35} This is not surprising because the high surface energy of noble metals

typically translates into a poor wetting of metal oxide surfaces, and in particular of titania.³⁶⁻³⁹ In fact, increasing the Au precursor exposure time from 5 to 40 min results in the formation of fewer but larger particles, as the average diameter grows from ~4 nm to ~15 nm, while the span of the size distribution (the difference between the maximum and the minimum observed diameter) grows from ~5 to ~21 nm (Fig 7.2a and c).

Diffuse Reflectance-Ultraviolet/Visible Spectroscopy (DRS) was employed to characterize the absorption properties of Au nanoparticles at different Au precursor dose times (Fig 7.2d). The absorption spectra show the emergence and evolution of the Plasmon resonance as the Au precursor dosage time is increased. With the growth of larger particles at higher loadings of Au, the absorption band narrows, the plasmon resonance shifts to lower wavelengths (from 576 to 536 nm), and the intensity of the plasmon resonance wavelength increases from 0.2 to 1.7 (Fig 7.2d). For Au nanoparticles smaller than 20 nm, the blue shift and narrowing of the absorption are attributed to the increase in particle size.⁴⁰⁻⁴² The intensification of the absorption is correlated with the increase in Au loading and particle size.^{12, 43} The DRS results, therefore, confirm the quantum confinement effects emerging in the ALD-grown nanoparticles and demonstrates the ability to tune them.

Figure 7.2: Evolution of the morphology, Au loading, and absorbance in the visible spectrum of the Au/TiO₂ obtained after 5 cycles with different precursor exposure times. (a) TEM micrographs of the Au/TiO₂ nanocomposites (scale bar 20 nm), (b) ICP results Au loading as the Au exposure time increases with corresponding photos of colloidal suspensions of the Au/TiO₂ nanocomposites (The dashed red line is drawn to guide the eye), (c) size distribution of the ALD-grown Au nanoparticles, (d) absorbance of the Au/TiO₂ nanocomposites as obtained via DRS measurements.

As synthesizing nanoparticles with an average size below 10 nm is essential for the catalytic applications of Au/TiO₂ nanocomposites, we focused on tuning the size distribution and the Au loading by tuning the exposures of the counter reactants while

using short Au precursor exposures. First, we studied the effect of varying the ozone exposure from 30 s to 10 min, while keeping the precursor and water exposure time constant at 10 min and 30 secs, respectively. The elemental analysis confirms that the Au loading on P25 nanoparticles is virtually unaffected by varying the ozone exposure over such a time window (Fig 7.3b). Nonetheless, the ozone exposure time has a dramatic effect on the size distribution of the ALD-grown nanoparticles, in that both the average size and the width of the size distribution are drastically reduced from 9.35 nm (std. dev. of 3.3 nm) to 4.68 nm (std. dev. of 1.0 nm) when the ozone exposure time is increased from 0.5 to 10 min (Fig 7.3a and d). Furthermore, the long tail that is observed at shorter ozone exposures gradually disappears with increasing exposure times. The fact that the loading is virtually unaffected by increasing ozone exposures, while the size distribution varies dramatically, suggests that the ozone changes the chemical affinity between Au and titania, and thus its degree of wetting and propensity to aggregate. XPS results confirm that the ozone affects the chemistry of the deposited Au as a significant decrease in Au (III) fraction is observed as the ozone exposure is increased (Fig 7.3c). Since ozone participates in the combustion reactions of the organic ligands remaining after the precursor chemisorption, an exposure to ozone is expected to promote the reduction of the deposited Au. At the same time, prolonged ozone exposures may also induce the formation of a thin oxide layer on the surface of the nanoparticles that promote their stability.^{38, 44-45}

Figure 7.3: Evolution of the morphology, Au loading, and chemical state of the Au/TiO₂ nanocomposites obtained after 5 cycles with different ozone exposure times. (a) TEM micrographs of the Au/TiO₂ nanocomposites (scale bar: 20 nm), (b) evolution of the Au loading with the ozone exposure time (The dashed red line is drawn to guide the eye), (c) evolution of the chemical state of the ALD-grown Au as captured by the Au 4f region of XPS spectra. [Fitted peaks in 0 s ozone curve show different oxidation states of Au (red Au(0), green Au(I) and blue Au(III)), (d) evolution of the size distribution of the ALD-grown Au nanoparticles with increasing ozone exposure times.

Next, the effect of water exposure was studied by keeping Au and ozone exposure at 10 min and varying the water exposure from 0 to 2 min. An analysis of the elemental composition by XPS and ICP shows no appreciable changes in the loading of Au on titania nanoparticles upon longer water exposures (Fig 7.4e, Supporting info Fig 7.2). Nonetheless, longer water exposures broaden the size distribution of the Au nanoparticles (Fig 7.4 a-d and f). These results suggest that water promotes surface mobility, and thus the propensity of adatoms and nanoparticles to diffuse and coalesce, while not affecting the amount of precursor that can chemisorb in every cycle.

Griffiths et al. performed a ternary Au ALD process on Si wafers using water as the second counter reactant to eliminate the phosphorus impurity.²⁹ Water would react with the phosphorous impurities producing phosphoric acid, which more readily desorbs from the growth surface. However, in our case, ICP-OES and XPS show no changes in the phosphorous content upon increasing the water exposure time (supporting info Fig 7.2). The ineffectiveness of water exposure in removing P can be attributed to the differences in the ALD environment and support material used here compared to the study by Griffiths et al. When the ALD process is performed in vacuum and on flat substrates with a surface area of $\sim\text{cm}^2$, several seconds of water exposure suffice to hydrolyze the phosphorus to phosphoric acid and purge the latter from the reactor. However, in our experiments, the high surface area of the powders ($\sim 100\text{ m}^2$) and the use of atmospheric pressure might hinder the removal of phosphorous. In fact, the removal of low-vapor-pressure substances, such as phosphoric acid, can be particularly slow in powders compared with flat substrates because of two phenomena: (1) capillary condensation, and (2) the fact that molecules that desorb from one particle can adsorb onto other particles before they can escape from the reactor.⁴⁶ In particular, the latter is exacerbated by operating the reactor at relatively high pressure compared with the vacuum reactors used by Griffiths et al.²⁹ The effective removal of phosphorus in the form of phosphoric acid would probably require much longer water exposures, which would be cumbersome as they tend to disrupt the fluidization behavior of the powders. Hence, the fabrication of phosphorus-free Au/TiO₂ nanocomposites via fluidized bed reactors operating at atmospheric pressure might require more aggressive treatments.

Next, the effect of varying the number of ALD cycles was studied using the following sequence of Au-O₃-H₂O exposure times: 10 min-10 min-30 sec. A 10 min nitrogen purge was applied after each precursor/co-reactant exposure. The Au loading shows linear evolution with the number of cycles in the range of 1-9 cycles (Fig 7.5 a). Increasing the number of cycles results in a slight increase in the average diameter of the ALD-grown nanoparticles, while the span of size distribution remains relatively constant (Fig 7.5 a-c and e). This is not surprising because a precursor exposure time of 10 min translates into a growth per cycle of only $\sim 0.26\text{ at/nm}^2$, which is 0.02 Au(111) ML. As a result, increasing the number of cycles from 3 to 9 would result in a total increase of $\sim 1.6\text{ at/nm}^2$, which in itself cannot result in an appreciable change in particle size. Hence, this clearly illustrates how the use of long ozone exposures in conjunction with short precursor exposures mitigates nanoparticle sintering in each

ALD cycle, and thus lends itself to the fine-tuning of the size of the ALD-grown nanoparticles down to the sub-nanometer level.

Figure 7.4: Evolution of the morphology and Au loading of the Au/TiO₂ nanocomposites obtained after 5 cycles with different water exposure times. (a-d) TEM micrographs of the Au/TiO₂ nanocomposites (scale bar 20 nm), (e) evolution of the Au loading (The dashed red line is drawn to guide the eye), (f) size distribution of the ALD-grown Au nanoparticles at different water exposure times.

The plasmon resonance peak measured from the samples with a varying number of cycles shifts towards lower wavelengths (578 to 544 nm) as the number of Au ALD cycles increases (Fig 7.5f). A stronger and narrower absorption band is also observed as a result of increasing Au loading upon increasing the number of cycles. As the Au particle size variation from the 3 cycles to 5 cycles experiments is less than one nanometer (4.5 to 4.7 nm), the detected shift in the resonance peak wavelength is almost negligible (~ 8 nm shift). On the other hand, the Au loading has a 40% increase from 3 to 5 cycles. This substantial change in the Au loading explains the enhanced resonance intensity and narrowing down of the plasmon resonance peak.

Figure 7.5: Effect of varying the number of cycles using long ozone exposures and short precursor exposures. (a-c) TEM micrographs of the Au/TiO₂ nanocomposites (scale bar 20 nm), (d) evolution of the Au loading with the number of cycles (The dashed red line is drawn to guide the eye), (e) Size distribution of the ALD-grown Au nanoparticles (f) Absorbance of the Au/TiO₂ nanocomposites as obtained via DRS measurements.

To further demonstrate the ability of our process to control the size distribution of the ALD-grown nanoparticles at a given Au loading, we tested the photocatalytic activity of the Au/TiO₂ nanocomposites towards the degradation of a model dye: Rhodamine B. Incorporating titania with Au nanoparticles has been reported to increase its photocatalytic activity towards various reactions, including the oxidation of organic molecules and water splitting.^{12, 47-50} Several mechanisms have been proposed in the literature to explain such an enhancement. For example, Au nanoparticles can extend the absorption of titania in the visible region because of plasmon resonance, and they can mediate surface charge recombination rates. In general, the effect of Au nanoparticles varies across different reactions and strongly depends on both the loading and the particle size. Although understanding the exact mechanism behind the enhanced photocatalytic activity of Au/TiO₂ towards the decomposition of Rhodamine B is beyond the scope of this work, we do show how the precision of our process can be used to decouple the effect of loading and particle size, and thus lead to optimal photocatalysts.

Figure 7.6: Photocatalytic activity of the Au/TiO₂ nanocomposites towards the decomposition of Rhodamine B with (a) varying both Au loading and particle size, (b) fixed particle size (5 nm) and varying Au loading, (c) fixed Au loading (2%) and increasing particle size.

First, we tested the photocatalytic activity of the nanocomposites obtained after five cycles using five different precursor exposures (Fig 7.6a), which translate into Au loadings that vary in the range ~1-7 wt% and particle sizes in the range ~5-15 nm. On these samples, the Au loading and the particle size are not decoupled as higher loadings correspond to larger particle sizes. As shown in Figure 7.6a, higher loadings, and thus larger particle sizes have a non-monotonic effect on the photocatalytic activity of the nanocomposites, as quantified in terms of the apparent rate constant (k_{app}) extracted from the decay over time of the Rhodamine B concentration upon illumination (Supporting info Fig 7.3). The rate constant increases threefold upon increasing the Au loading to ~5 wt% compared with bare TiO₂. Yet increasing the loading further sees a gradual drop in k_{app} . Although a maximum exists, loading and particle size are coupled and so it is not clear whether this trend is to be attributed to the loading or the particle size. This exemplifies one of the common problems encountered in fundamental studies into the catalytic activity of nanostructured materials.

To illustrate how our process can be used to gain insights into the structure-dependent properties of Au/TiO₂ nanocomposites, we studied the photocatalytic activity of samples obtained by decoupling the Au loading from the particle size. Figure 7.6b shows that for a given particle size (5 nm), k_{app} increases roughly linearly with the Au loading in the range ~0.5-5 wt%. On the other hand, Figure 7.6c shows that at a given loading (~2.1 wt%), k_{app} rapidly decreases with increasing particle size (in the range ~4-10 nm), and approaches the value obtained for the control case with bare TiO₂ for a particle size around 10 nm and larger. A similar trend was reported in the seminal work by Haruta⁹, where they show that the catalytic activity of Au nanoparticles towards CO oxidation rapidly decreases with increasing particle size, and virtually vanishes beyond 10 nm.

7.4. CONCLUSION

We demonstrated ALD of Au on gram-scale batches of titania nanopowders using a thermal process employing a fluidized bed reactor operated at atmospheric pressure. We performed ALD at the relatively low temperature of 105 °C using trimethylphosphino-trimethyl gold (III) as the metal precursor and ozone and water as co-reactants. This process leads to the formation of supported Au nanoparticles, with the number of cycles controlling the Au loading. We found that by varying the exposure time of the co-reactants, it is possible to control the broadness of the size distribution of the Au nanoparticles independently from the Au loading. In particular, ozone and water exposures have opposite effects: long ozone exposures suppress nanoparticle sintering and thus result in narrow size distributions, whereas long water exposures lead to broad ones. By leveraging the ability of the process to control the particle size at given loading, we could explore the structure-property relationship of the ALD-grown Au/TiO₂ in the photocatalytic degradation of Rhodamine B. We could achieve up to a threefold increase in the photocatalytic activity of titania by increasing the Au loading in the range 0-5 wt% while maintaining a constant nanoparticle size of ~5 nm. Conversely, increasing the nanoparticle size from 5 to 9 nm at the given loading of ~2.1 wt% resulted in a decrease of the photocatalytic activity, which gradually approached that of bare TiO₂. This process opens new avenues not only for the scalable fabrication of Au/TiO₂ nanocomposites, but also for investigating the structure-property relationship of supported Au nanoparticles.

Outlook and conclusions

8.1. GENERAL OUTCOME

This thesis focuses on the development of improved photocatalysts to degrade organic pollutants in water. Starting with TiO₂ (P25) particles as photoactive material, we were able to utilize the precise controllability of atomic layer deposition (ALD) using various deposits (Chapter 2: Pt, Chapter 3: Cu₂O, Chapters 4 & 5: SiO₂, Chapter 6: a combination of SiO₂ and Pt, and Chapter 7: Au) increasing the photocatalytic activity. The deposition of Cu₂O clusters and SiO₂ layers on P25, respectively, provided noble metal-free photocatalysts with superior photocatalytic activity. This gives the opportunity to reduce the costs of photocatalysts, while keeping the improvement factor at the same level or even higher than noble metal catalysts such as Pt:TiO₂ (P25) (Table 8.1). Mechanistic studies for SiO₂:TiO₂(P25) revealed the change in the mechanism for P25 from direct oxidation on the surface to a more hydroxyl-based mechanism for the degradation of dyes upon deposition of SiO₂. Furthermore, this change resulted in a different selectivity for the degradation of multiple compounds in the water, which adds complication to the evaluation of different materials that differently perform when it comes to photodegradation of multiple components in a system. Moreover, revealing the working principles of the Pt modified P25 catalyst demonstrates how modifications of a base material can affect the performances of photocatalysts under different atmospheres O₂ and Ar, respectively.

Table 8.1: Cost of the P25 and chemicals used in this thesis to deposit modifications on the surface of TiO₂ (P25) and improve its photocatalytic activity. The cost of the gold deposition could not be calculated, since the precursor is not commercially available.

Catalyst Material	P25	Pt:P25	Cu ₂ O:P25	SiO ₂ :P25	Pt:SiO ₂ :P25	
Precursor	-	Pt(Me) ₃ CpMe	Cu(hfac) *SiC ₂ H ₃ (Me) ₃	SiCl ₄	SiCl ₄	Pt(Me) ₃ CpMe
Price [€/g]	1.61	254.00	6.89	0.53	0.53	254.00
Molar mass [g/mol]	-	319.3	370.5	169.9	169.9	319.3
Supplier	Sigma Aldrich	Strem Chemicals	Gelest	Sigma Aldrich	Sigma Aldrich	Strem Chemicals
Optimal loading [wt. %]	-	0.36 (Pt)	0.40 (Cu)	1.80 (Si)	1.20 (Si)	0.62 (Pt)
Price catalyst (coating only) [€/kg]	1610.00	3107.27 (1497.27)	1770.81 (160.81)	1668.08 (58.08)	4227.35 (38.72) (2578.63)

Price / Enh. factor	1610	1554	885	556	705	

Furthermore, using ALD in a fluidized bed offers the opportunity to produce high-surface-area photocatalyst material (P25: 55 m²/g) of up to 5 g per batch. More importantly, ALD provides precise tunability of the loading (Chapters 2 to 7) and the cluster size of deposits (especially in Chapter 7).¹ In all of our studies, we find that optimal performance can be achieved with only minute loadings (for layers (SiO₂) and clusters (Pt, Au, and Cu₂O)). This advocates the importance of controllability to develop high-performance catalysts. In case of SiO₂ the layer thickness (1.2 nm optimal thickness) determines the photocatalytic activity, for Pt and Cu₂O modification only very low loadings (0.34 wt. % Pt, 0.4 wt. % Cu) give a further improvement while Au clusters of very defined particle size (5 nm) were most active. These results advocate the advantages ALD provides to the controllable design of optimized photocatalytic materials.

8.2. LIMITATIONS OF THE USED APPROACH AND RECOMMENDATIONS FOR FURTHER IMPROVEMENT

We have shown that ALD has excellent potential in catalyst improvement, especially when very low loadings or layer thicknesses are required. The scalability and depositions under atmospheric pressures are a great benefit for developing this technique further for catalyst manufacturing. However, despite the pure gas-phase deposition, which makes the use of solvents as a source of contamination redundant, ALD deposits often deal with contaminations from precursors, too. For the deposition of SiO₂ layers, we have shown in Chapter 3 how the residual contamination Cl from the SiCl₄ precursor can adversely affect the photocatalytic activity. Nevertheless, simple post-treatment could reduce the contamination leading to improved photocatalytic activity. Other than for SiO₂, during ALD of Au in Chapter 7, the P residues seem to be very persistent on the surface, which possibly affect the photocatalytic performance, and further treatment should be explored to remove those supposedly harmful contaminants.

The studies in this thesis were mainly based on the degradation of dye molecules. However, lately, the discussion in literature arises whether the degradation of dye molecules is a suitable experiment to evaluate the photocatalytic activity of newly developed materials also for water purification.²⁻³ Due to the capability of absorbing solar light, specific dye molecules themselves may be excited and degrade instantly (self-degradation) or, secondly, inject excited electrons into the catalyst material, which leads to the degradation of the dye molecule. Preliminary photocatalytic tests under visible light for SiO₂:TiO₂(P25) and Cu₂O:TiO₂(P25) showed however, no catalytic activity indicating the absence of the self-sensitization for those catalytic systems. Nevertheless, this issue should be further investigated in follow-up studies. Additionally, the electron injection mechanism may only occur when the dye molecule is able to adsorb on the surface. In our studies, we both checked for self-degradation without a catalyst and we addressed the second issue by testing the degradation of dye

molecules, which have different charges leading to both attractive and repulsive interactions with the catalyst surface. Furthermore, the possibility to diminish the photocatalytic activity under certain conditions (Ar atmosphere, scavenging agents) also shows that the degradation of the dye molecules via self-degradation cannot be the main contribution for the degradation. Additionally, experiments using a light source emitting photons of lower energy than the bandgap of the photocatalyst would further clarify the role of the dye electron injection mechanism. Apart from these issues, in order to further investigate the general photocatalytic activity of the developed materials, as a next step more contaminants (herbicides, pesticides, pharmaceuticals) need to be tested to thrive to implementation of the technology into real life. Especially the simultaneous degradation of multiple pollutants may change the overall efficiency and selectivity of pollutant degradation (Chapter 5).

Even though numerous analysis tools have been developed to investigate the mechanistic pathways in photocatalysis, many techniques do not give a clear solution since the results depend on different parameters. A precise analysis of the influence of different parameters remains challenging and often ambiguous. As we have seen in Chapter 5, the addition of sacrificial agents (DMSO, MeOH) may be helpful in investigating the predominant degradation pathway. However, the apparent role of those molecules in the photocatalytic mechanisms is not entirely resolved. Ideally, mechanistic insight would arise from the deconvolution of different parameter and their individual influence on the photocatalytic activity. Therefore, experimental design and understanding of interaction with different pollutants and especially sacrificial agents need improvement to manifest conclusions. Well understood model systems to test the activity, and in-situ measurements of the radical generation and charge carrier kinetics may help to further understand the underlying principles for specific materials.

Furthermore, the possibilities to evaluate photocatalytic activities and especially compare them still lack so far because of the various ways of testing a photocatalyst. Standardized testing of catalysts in a specific environment (reactors, light spectrum & intensity, irradiation area, atmosphere) would increase the comparability between materials in publications. The goal should be to determine the intrinsic activity of a material per surface area. Using slurry systems to test the activity is the most commonly used and easiest way to measure the photocatalytic activity of a powder photocatalyst. However, two regimes can be chosen to evaluate the activity: high and low catalyst concentration. ⁴ High catalyst concentration prevents the scattering of incoming light out of the reactor. A photon that is not absorbed but scattered by a catalyst particle is then likely to be absorbed by another catalyst particle in the slurry. However, as a result of the high catalyst concentration in the slurry, the light may only partially penetrate into the slurry, leaving a significant fraction of the particles not irradiated. Furthermore, the effect of agglomeration of particles for high concentration has shown to have a substantial effect on the apparent kinetic constant due to mass transport limitation from the dye solution into the agglomerates. ⁵ Low catalyst concentration could prevent the mass transport limitation due to limited agglomeration and would make sure all particles are homogeneously irradiated. For low concentrations,

a kinetic regime can be reached where the catalyst concentration scales linearly with the activity indicating that mass transfer limitations play only a negligible role anymore.⁵ The light scattering properties, i.e. absorption coefficient, on the other hand, of differently modified materials, will become more prevalent at low catalyst concentrations. However, measuring and correlating the scattering index with the kinetic constants would give in this case the intrinsic kinetic constant of materials per surface area. This would not only make the comparison between materials easier but also would give the chance to translate experimental results of the catalyst activity to reactor modeling and reactor design. Additionally, revealing the mechanism of certain modifications could not only lead to better understanding of the working principles but also a smart catalyst design could be pursued. Combining materials which modify different parts of the photocatalytic mechanism individually such as the combination of enhanced adsorption with improved surface reactivity would strongly increase the photocatalytic activity of these smartly designed new materials. ALD with its precise controllability of material deposition on the surface could play an important role in the specific design of these materials.

After initially evaluating the photocatalytic activity in defined lab environments, the translation to more complex systems with various parameters such as additional ion concentration needs to be taken into account. The problem here is that for different added molecules, the activity does not change similarly for different catalysts. In that regard, the effect of substances such as dispersing agents e.g. sodium polyphosphate, is still unresolved, leading to different activity trends upon addition for i.e., P25 and Pt:TiO₂(P25). This makes it almost impossible to predict the activity of a catalyst in a different environment unless the mechanisms are clearly resolved. In the case of an application for water treatment, this makes the technology unreliable for unknown water sources and negates the technology as applicable for general water treatment. On the other hand, numerous reports have shown progress in the revelation of mechanism and trends in activity in the presence of other pollutants or ions.⁶⁻⁷ Therefore, evaluating the excellent potential of photocatalysis, especially in an area where conventional treatment technologies reach their limits such as the removal of micropollutants, I would recommend focusing photocatalysis first towards the treatment of special effluents of manufacturing plants or hospitals. In those, the water contamination is more defined and stable and the combination with other treatment technologies is more feasible and affordable. After successful implementation in this area, the next step should then thrive to implementation of photocatalysis to provide clean drinking water from a polluted water source to people in low-resource settings.

SAMENVATTING

Fotokatalysatoren gebruiken, anders dan conventionele katalysatoren, licht om een reactie te activeren. Door het absorberen van fotonen raken elektronen geëxciteerd en bereiken ze hogere energietoestanden om een redoxreactie te starten. Dit principe kan gebruikt worden om chemicaliën te produceren zoals waterstof via de reductie van water of om koolstofdioxide om te zetten naar brandstoffen, zoals methaan, methanol en formaldehyde. Naast productie van chemicaliën kan de reductieve/ oxidatieve potentiaal van de geëxciteerde elektronen/gaten gebruikt worden om moleculen af te breken. Dit is vooral handig voor zelfreinigende materialen of het verwijderen van organische moleculen, zoals kleurstoffen, pesticiden of farmaceutica uit afvalwaterstromen. Dit is nuttig omdat toenemende watervervuiling steeds meer de menselijke gezondheid schaadt, met name in ontwikkelingslanden. Ondanks het grote potentieel en uitgebreid onderzoek gedurende de laatste decennia, is de ontwikkeling van goedkope en efficiënte fotokatalysatoren en goed inzicht in van het mechanisme van fotokatalytische degradatie nog steeds niet in zicht; dit zit de vertaling van het laboratorium naar de applicatie in de weg. TiO_2 (P25) is een goedkoop en niet-giftig fotoactief materiaal, maar te inefficiënt voor waterreiniging. Dit proefschrift zal zich focussen op de modificatie van TiO_2 (P25) en op de evaluatie van de fotokatalytische mechanismen. Atoomlaagdepositie (ALD) geeft ons de mogelijkheid om de depositie van vele verschillende materialen exact te kunnen besturen op atomaire schaal, een voordeel dat het ontwerp en de activiteit van de fotokatalysator kan verbeteren.

Ondanks de geavanceerde ontwikkeling van Pt: TiO_2 (P25) als een fotokatalysator is het mechanisme van fotokatalytische degradatie nog steeds niet volledig opgehelderd. De deconvolutie van katalytische effecten is cruciaal voor de analyse en evaluatie van het fotokatalyse mechanisme om de mogelijke nadelen te identificeren en deze kennis te gebruiken om katalytische materialen te verbeteren. In Hoofdstuk 2 worden de dominante katalytische parameters een voor een geanalyseerd om de rol van Pt clusters op Pt: TiO_2 (P25)-nanodeeltjes op te helderen voor de degradatie van organische kleurstofmoleculen. Het is ons gelukt om de verbeterde adsorptie van opgelost O_2 op Pt clusters op TiO_2 (P25)-deeltjes te bewijzen, resulterend in verbetering van de fotokatalytische degradatie van organische kleurstofmoleculen. Pt: TiO_2 (P25) functioneerde slechter als fotokatalysator in een inerte atmosfeer als gevolg van lading recombinatie en een gebrek aan O_2 , wat het belang van correcte werkomstandigheden voor bepaalde katalytische materialen aantoont.

Het gebruiken van metaaloxiden in plaats van edelmetalen in fotokatalysatoren zou de kosten significant kunnen verminderen. De depositie van Cu_2O op TiO_2 (P25), als een goedkoper alternatief voor edelmetalen zoals Pt, kan resulteren in een verbeterde ladingsscheiding door gunstige energiebandposities van Cu_2O in vergelijking tot TiO_2 . Het is ons gelukt om Cu_2O nanoclusters te deponeren op het oppervlak van TiO_2 (P25) deeltjes door ALD in een gefluïdiseerd bed te gebruiken (Hoofdstuk 3). Dankzij de zelflimiterende ALD-reacties konden we de hoeveelheid Cu_2O clusters op het oppervlak controleren. Een zeer lage hoeveelheid Cu_2O op TiO_2 (P25) (0.4 wt % Cu) vertoonde een dubbele fotokatalytische activiteit voor de degradatie van verschillende kleurstofmoleculen vergeleken met puur P25.

Een nog goedkoper en stabiel materiaal is SiO₂. Ondanks de inactiviteit van SiO₂ voor fotokatalytische reacties, zorgde een ultradunne coating van SiO₂ op P25 voor een toename aan fotokatalytische activiteit van 100% (Hoofdstuk 4). Door de exacte dikte van de SiO₂ coating te controleren is het ons gelukt om de fotokatalytische activiteit aan te passen van versterking (<1.2 nm) tot onderdrukking (>1.2 nm) met een optimale activiteit voor een coatingdikte van 0.7 nm. De oorsprong van de katalytische verbetering van SiO₂:TiO₂(P25) deeltjes is getest door twee tegengesteld geladen kleurstofmoleculen te gebruiken om het effect van adsorptie op de fotokatalytische verbetering te onderzoeken. Scavengers onthulden een verandering in het degradatiepad van directe oxidatie (P25) naar hydroxyl-radicaal-gebaseerde degradatie als resultaat van de meer zure OH-groepen aan het SiO₂ oppervlak. Dit leidt tot minder selectieve degradatie van meerdere verontreinigingen, wat met name handig is voor de simultane degradatie van meerdere verontreinigingen (Hoofdstuk 5).

Door de verkregen inzichten van Hoofdstuk 2 en 5 te gebruiken hebben we een nieuw fotokatalysator ontwikkeld door een materiaal te synthetiseren met een dun laagje SiO₂ op TiO₂ (P25), gevolgd door de depositie van Pt-clusters met de intentie om de voordelen van beide gedeponeerde materialen in een enkel materiaal te combineren. Pt:SiO₂:TiO₂(P25) toonde een verdere verbetering in de activiteit van de fotokatalytische degradatie van Acid Blue 9 (6x beter dan P25), waarbij de optimale belading van SiO₂ en Pt op P25 op het gecombineerde materiaal vergelijkbaar zijn met de enkelvoudig aangepaste materialen SiO₂:P25 en Pt:P25 (Hoofdstuk 6). Dit toont aan dat de combinatie van meerdere materialen de deur opent naar verdere katalytische verbeteringen door het gebruik van ALD.

Als een alternatief voor Pt kunnen Au-deeltjes voordelige eigenschappen hebben als co-katalysatoren voor de fotokatalytische degradatie van organische verontreinigingen. Wij hebben als eersten in een gefluïdiseerd-bed-ALD-reactor Au-clusters gedeponerd op TiO₂(P25)-nanodeeltjes bij atmosferische druk (Hoofdstuk 7). Los van zelflimiterend gedrag konden we grootte van de Au-clusters manipuleren door de duur van de oxidator-puls aan te passen. Dit is vooral interessant aangezien het de mogelijkheid geeft om cluster-groottes te variëren terwijl de Au lading constant blijft. De fotokatalytische activiteit voor verschillende Au-cluster-groottes varieerde, wat het belang van controleerbaarheid van zowel lading als ook cluster grootte voor katalytische toepassingen benadrukt.

Atoomlaagdepositie in een gefluïdiseerd bed biedt dus uitstekende controle over oppervlaktemodificaties om de fotokatalytische activiteit van TiO₂(P25)-nanodeeltjes te verbeteren. Dit proefschrift beschrijft verschillende benaderingen om de fotokatalytische activiteit te verhogen zoals de verbetering van de reactantadsorptie voor Pt:P25 (Hoofdstuk 2), de verbetering van de ladingsverdeling voor Cu₂O:P25 (Hoofdstuk 3), en de verbetering van de oppervlakte-activiteit voor SiO₂:P25 (Hoofdstuk 4). Verder tonen de resultaten aan dat ALD een zeer veelzijdige techniek is om multicomponent fotokatalysatoren te synthetiseren om zo de fotokatalytische eigenschappen te kunnen afstemmen en de materialen te verbeteren voor toekomstige implementatie.

SUMMARY

Photocatalysts, contrary to conventional catalysts, utilize light to drive a reaction. By absorption of photons, electrons are excited and reach higher states to initiate a redox reaction. This principle can be broadly used to produce chemicals such as hydrogen via the reduction of water or transform carbon dioxide into solar fuels, i.e., methane, methanol, and formaldehyde. Besides chemical production, the reductive/oxidative potential of the excited electrons/holes can be utilized to degrade molecules. This is especially useful for self-cleaning materials or for cleaning waste water streams from molecules such as dyes, pesticides, or pharmaceuticals, as water pollution levels increasingly harm human health, especially in developing countries. Despite the great potential and vast research activities over the last decades, the development of cheap and efficient photocatalysts and especially the evaluation of the mechanism of photocatalytic degradation pathways are still lacking, which hampers the translation from lab to application. TiO_2 (P25) is a cheap and non-toxic photoactive material, yet too inefficient for water cleaning. This thesis focuses on the surface modification of TiO_2 (P25), minimizing various drawbacks of TiO_2 (P25) and on the evaluation of the photocatalytic mechanisms. Atomic layer deposition (ALD) allows us to precisely control the deposition of many different materials at the atomic level, an advantage that could improve the photocatalyst design and optimize the activity.

Despite the mature development of Pt: TiO_2 (P25) as a photocatalyst, the mechanism for photocatalytic pollutant degradation is still under discussion. The deconvolution of catalytic effects is crucial for the analysis and evaluation of the photocatalysis mechanism in order to identify drawbacks and use this knowledge to improve catalytic materials. In Chapter 2, the dominant catalytic parameters are evaluated separately to clarify the role of Pt clusters on TiO_2 (P25) nanoparticles for the degradation of organic dye molecules. We were able to prove the beneficial role of dissolved O_2 on Pt clusters on P25 particles resulting in the photocatalytic improvement on the degradation of organic dye molecules. Pt: TiO_2 (P25) performed worse as a photocatalyst in an inert atmosphere as a consequence of the charge recombination and a lack of O_2 , which demonstrates the importance of the correct working environments for certain catalyst materials.

Moving away from photocatalysts containing noble metals to metal oxides would significantly decrease the cost. The deposition of Cu_2O on TiO_2 (P25), as a cheaper alternative to noble metals such as Pt, may result in an enhanced charge separation due to the aligned band positions of Cu_2O compared to TiO_2 . We were able to deposit Cu_2O nanoclusters on the surface of TiO_2 (P25) particles using ALD in a fluidized bed (Chapter 3). The self-limiting ALD characteristic allowed us to precisely control the loading of the Cu_2O clusters on the surface. Very low loaded $\text{Cu}_2\text{O}:\text{TiO}_2$ (P25) (0.4 wt % Cu) demonstrated a double photocatalytic activity for the degradation of several dye molecules compared to bare P25.

An even cheaper and more stable material is SiO₂. Despite the catalytic inertness of SiO₂ for photocatalytic reactions, an ultrathin overcoating of SiO₂ layers over P25 increased the photocatalytic activity by 100 % (Chapter 4). By precisely controlling the thickness of the SiO₂ coating, we were able to tune the photocatalytic activity from enhancement (<1.2 nm) to suppression (>1.2 nm) with an optimum activity at a coating thickness of 0.7 nm. Evaluating the origin of the catalytic improvement SiO₂:TiO₂(P25) particles were tested using two differently charged dye molecules to investigate the effect of adsorption on the photocatalytic improvement. Scavenging agents revealed a change of the degradation pathway from direct oxidation (P25) to hydroxyl radical based degradation as a result of the more acidic surface OH groups on the SiO₂ surface. This leads to less selective degradation of multiple pollutants, which is especially useful for the simultaneous degradation of multiple pollutants (Chapter 5).

Using the insights gained in Chapters 2, 4, and 5, we designed a new catalyst material by building up a material with a thin layer of SiO₂ on TiO₂(P25), followed by the deposition of Pt clusters to use both materials' advantages in a single material. Pt:SiO₂:P25 exhibited a further improvement in the activity for the degradation of Acid Blue 9 (6x better than P25), where the optimal loading ranges of SiO₂ and Pt on P25 in the combined material are similar to the mono-modified materials SiO₂:P25 and Pt:P25 (Chapter 6). This demonstrates that the combination of multiple materials opens the door to further catalyst improvement using ALD.

As an alternative to Pt, gold particles may have advantageous properties as cocatalysts for the degradation of organic pollutants. For the first time in a fluidized bed ALD reactor, we deposited gold clusters on TiO₂ (P25) nanoparticles at atmospheric pressure (Chapter 7). Apart from self-limiting behavior, we could control the gold cluster size by modifying the pulse duration of the oxidizer pulse. This is especially interesting since it provides the opportunity to vary cluster size while keeping the Au loading constant. Moreover, the photocatalytic activity varied for different Au cluster sizes, which stresses the importance of controllability over both loading and cluster size for catalytic applications.

It can be concluded that atomic layer deposition in a fluidized bed provides excellent control over surface modifications to improve the photocatalytic activity of TiO₂ (P25) nanoparticles. This thesis demonstrates different approaches to improve the photocatalytic activity such as improving reactant adsorption for Pt:P25 (Chapter 2), improving the charge separation for Cu₂O:P25 (Chapter 3), and improving the surface reactivity for SiO₂:P25 (Chapter 4). Moreover, the results demonstrate that ALD is a very versatile tool to built up multicomponent photocatalysts to further tune and improve the photocatalytic properties in a material needed for future implementation.

ACKNOWLEDGMENTS

Writing this part of my thesis means that I have reached the end of a major chapter in my career. This book should prove that I reached a state where I can defend my work during the last four years and the achievements I accomplished in this process. However, without the contributions of so many different people, specifically my supervisors, collaborators, friends, and family, this book would be just an exotic thought of a young fellow from a small village in the middle of Bavaria. Therefore, I would like to take this opportunity here to express my sincerest gratitude to the people who supported and followed me throughout this journey.

I want to start thanking the person who had a big contribution to me actually coming to Delft and choosing the path of the PhD. Julien, your guidance and supervision during my BSc thesis and MSc thesis inspired me and enormously helped me to develop as a scientist. Your positive attitude and commitment towards students made my time in your group in Erlangen a great pleasure both from a personal and scientific point of view. Your enjoyment of helping and guiding me during my time in Erlangen by a situation where I dropped by your office late afternoon for a short question which turned into a personal two hour lecture about electrochemistry until you remembered that you should finish a proposal due at midnight. I always enjoyed coming back to Erlangen for a visit and observe how great your group is developing. I am delighted that you agreed to be part of my defence committee so that you not only pathed me the way to explore new frontiers here in Delft but also (hopefully) the successful defence of my PhD thesis.

Ruud, thank you for giving me this opportunity to follow the way of a PhD candidate and guiding me until the end. It was a great journey where I learned a lot about executing research independently, and I am very grateful for the opportunities you gave me. I appreciate that you had always an open door for me so I could be sure that in case I need help you will be there to help me overcome the obstacle. Besides the work environment, I appreciate your competitiveness in various fun occasions during our group activities (e.g. karting or the eggrun). Competing against you gave a nice flavour to the whole PhD experience, even though in case of a loss I would need to listen to that story for some time - but that makes the next win even sweeter.

Hao, I would like to thank you for guiding me through the first and final stage of my PhD, and I would like to express my sincere gratitude for giving me the opportunity for a research stay at Phenikaa University in Vietnam. It was one of the highlights during my time as a PhD candidate to experience a completely different environment. Your welcoming attitude and helping hand from booking a taxi to showing me the typical Vietnamese cuisine and finding me local travel guides made my stay an unforgettable experience.

Bert, even though you joined as a supervisor past the halfway mark I can consider your contribution one of the largest. You helped me to look even more critically at my results

and challenged me in situations where I thought I considered it all. Your direct feedback and very valuable comments significantly raised the quality of this thesis.

Michiel, you helped me very much to broaden my horizon in how to execute research. Despite the limited interactions we have had, your feedback was always on point and helped me to look at my results from a different angle. Thank you for hosting the Christmas dinner and summer BBQ, it was always great fun to bring the group together outside of the department walls.

I would also like to thank Prof. Sammy Verbruggen, Prof. Luuk Rietveld and Prof. Bernard Dam for taking the time to evaluate my doctoral thesis and being part of the defence committee and appreciate your feedback to make this thesis stronger.

Besides the scientific part without the help of secretaries in and outside of PPE writing this thesis would have taken quite a bit longer. Elly, Jennifer, and Leslie thanks a lot for taking care of any organizational part of my PhD journey and providing valuable advice in various situations. Caroline, thank you for taking care of sending my samples around the globe and making sure they arrive safely. Karin and Astrid, thank you for making my life easy in booking progress meetings Michiel or numerous signature requests.

Mojgan, you kept the lab running and your calm and caring attitude was infectious. Especially after these days were nothing seemed to work and all experiments (and setups) failed your helping hands made sure we could proceed with success. Aris, your “short” intermezzo at PPE brought the level of lab organization to a new level. Your drive to help people wherever you can and your experience in the ALD world made not only every discussion very fruitful but also super enjoyable. Stefan, whenever it came to a homebuilt part you were the person to get in touch with. Your skills were essential to keep our dear ALD systems operational and updated. Thank you for that. Kristen, thanks for letting me “steal” components from your biolab to keep my experiments going without a delay. Bart, Liliana and Willy, without your skills and knowledge in the field of catalysis engineering I would have struggled way more to get the results I can now present in this thesis. Thank you for letting me expand in your lab and being so helpful in executing experiments and troubleshooting the equipment. Ruben, thank you for your help in the UV/Vis measurements and Armand for introducing me to the experimental opportunities in the Waterlab. Bart, I will remember you always being the firefighter for any Labview issues of our ALD systems. The issues we ran into were numerous and what impressed me was your positive approach to the problems and your continuous will to fix the issues we were presenting to you. Additionally, thanks for making sure that the XPS was up and running as much as possible and therefore providing a smooth operation. Wiel, I can’t recall the number of times I was stuck at the TEM machine/software. Nevertheless, you were always available and provided a speedy solution so I could continue without much delay. Thank you!

Pouyan and Volkert, despite our interaction was mainly based on the journal club, you helped me getting out of my comfort zone to explore new fields of science and discuss

the outcome in vibrant discussions. Gabriele, it is great to see how you interact with the people around you, always trying to find solutions which fit both sides. I really want to thank you your input on my future development both scientifically and personally. Henk, thank you for being part of my supervisory team in the beginning of my PhD. Even though our interaction was unfortunately short – I hope you enjoy your retirement to the fullest – you had a great influence on the development of me and my project in the early stage.

During my time as a PhD student I got the opportunity to collaborate with many different people, who certainly had a big impact on the outcome of this thesis. Thanks to the group of Prof. Rik van Deun at the University of Ghent for hosting me so willingly for the photoluminescence measurements. Prof. Jorg Thöming, thanks for hosting me in your research group in Bremen to learn about DLS measurements, and Jan, I really appreciate your patience and helpfulness in measuring my samples. Ina, thank you for helping me out on the FTIR measurements and your patience in answering all my questions about the possibilities in characterization methods in catalysis engineering. Kevin, your dedication towards collaboration was a blessing for me. Thank you for being so eager and helpful with the TRMC measurements and always having an open door to discuss with me the results.

The supervision of numerous students was always a pleasure for me. Thank you, Alain, Francesco, Jonathan, Mohammed, Mourijn, Egem, Floris, Roel, Sophie, Vanessa, Ankit, and Dylan. I really enjoyed working together with all of you to try to solve the problems we were facing during this research together. I greatly appreciate the work you put in to make this research successful. It was always a pleasure to discuss the results with you, and I was impressed about the different points of views you brought into this project. I wish you all the best for your future and it would be great if I could read some research work from you in the future.

I would like to thank everyone in the Delft Global Initiative. When I heard the first time the plans you had about bringing research to people in need, it really triggered me. It was one of the main reasons to apply to the project about water treatment. The working culture and the pure dedication to make things possible in an area often overlooked was a genuinely inspiring experience. It was great to see how you pushed forward the needs of people who are not as privileged as we are. I am honoured to have been part of that very active community and to see other projects flourish to have a real impact on society. Jennifer and Claire, thank you for putting this program together and allow me to be part of that. Friso and Sophie, thanks for the great lunches and high quality lunch talks which helped me to broaden my horizon and experience many different angles of how we as a society can tackle the severe problems occurring and arising in different parts of the world. But most importantly, I would like to thank all my Delft Global fellows – Anteneh, Camille, Christine, Hendrik, Henry, Juan Carlo, Juan, Merel, Michel, Mona, Nishant, Petra, Pieter, Rachel, Roos, Saqr, Tope, Yask, Mitasha. It took us a while in the beginning to understand what Delft Global Fellow actually means, but we certainly knew from the start that it was something special and we were all proud

to be in there. It was really great to talk and listen to your very diverse research, sharing experiences being jealous of each other's research trips and learning from both defeat and success in the individual research. Keep up the great work you are doing, and I am very much looking forward to the outcome and wish you the best of luck and success in making the world a better place with your research.

Andris and Aswin, I could not have asked for better paranymphs for my doctoral defence, even though the corona crisis might take away this honour. Andris, it was such a great honour to share the Ultimate field with you both at Force Elektro and the National Team, share shelter, then a proper accommodation and so many great experiences and memories around my frisbee career. With you around, I was sure to accomplish great things and to push greater heights outside academia. Your combination of competitiveness and fun gave a great mixture for suffering with fun both on and off the field. The fact that we could discuss for literally hours whether acting or reacting is easier for people and still come to an agreement at 3 am shows how our strong personalities fit so well together. Thank you for sharing the successes with me but especially in defeat for lifting me up and providing with valuable advice. Aswin, there was a time in the beginning where I thought it would be difficult to find a good connection. I am very glad that I was so wrong about my judgement. Having you as an office mate was key for me to survive the challenging days in the office always being available for a ranting session to release pressure and focus back on the good things. I know I can trust you in making fun both with and of me in good times but, more importantly offer your help in difficult situations. Your wisdom and calmness contributed so much to me standing here to be able to defend my PhD work.

Shaurya, for no person I would like to exchange you as an office mate. Experiencing your enlightenment was such a great experience and helped me so much to look at things from different angles. The fun we created in our office was just on a higher level. I truly think that we both defined new physical laws by being able to pull each other out of the same pit sometimes being stuck in. Me carrying you through the survival run was just a small payback for the carrying you did for me during our time in the office. Maulik, your calm and considerate way of dealing with things impressed me a lot. Seeing you in situations where others would certainly have broken carried me where situations got tight. It was a pleasure to return this favour at the survival run. Kartik, I admired your perseverance in how you approached your PhD project. It was fun to see how you prepared yourself with your spicy food for the challenges of the PhD journey. Damiano, I think I got the best compliment I can receive from an Italian by officially announcing that my homemade pizza is eatable. It was always fun to discuss with you why pineapple on a pizza is a crime, but Nutella is fine on the other hand. I admire your work attitude digging deep into topics not only related to your research but also starting your own investigation on various topics such as corona crisis and providing always very valuable information. Samir, your fun attitude was the reviving force in PPE. It was always fun to have you around because there was a certainty that any bad mood was gone in no time. Thanks, Isabell, Zaid and Georg for bringing new spirit into PPE and initiating the restart of Friday drinks to keep a social touch. Ruben, thanks for accepting

my push up challenges and competing with you for the top on the whiteboard and for your help to translate my thesis summary into Dutch. Dayinta, Durgesh, Andrea, David, Fabio, Melvin, thank you for your advice and make me feel at home in the early stage with all the borrels. I also would like to thank all other current and former group members of PPE for being part of my journey here at TU Delft and filled it with memories I will never forget: Alvaro, Yujie, Jing, Fuweng, Feilong, Josette, Erik, Hamid, Saeed, Abtin, Serhii, Afshin, Alessandro, Qian.

Sid and Manas, you brought PPE and TP closer together by seeking those cross-group activities, organizing borrels, and introducing me to Bollywood movie culture. Sid, thanks for being founding father of the “one last drink” at Doerak. Your passion for art impressed me a lot which was a nice change to the pragmatic PhD research. Robert, having you as a German fellow in the office next door was so refreshing. Thanks for your numerous help in the CE lab and it was always fun to trash talk with you to keep the mood up.

I recommend everybody during a PhD to diversify to other areas to accomplish things in a different environment, since it is unavoidable to face stressful, challenging, and disappointing situations. For me playing Ultimate Frisbee with Force Elektro was the ground to recharge, enjoy the sport I love and share the emotions during wins and losses, training in hail and sunshine and working out together. Ravi, Richard, Stidge and Andris it was so great to see how you initiated the reanimation of Force Elektro’s competitiveness. You built the foundation for the future success and I learned a lot as a coach and player from you. Ravi and Ingeborg, I don’t know what I would have done without you, giving me shelter in your house. There are no words to express my appreciation. Hosting movie nights, game nights and just discussing about our most favourite topic – Ultimate Frisbee – was such a help to free my head and refocus. Because of you guys I got the chance for so many new experiences, going to Windmill Windup and play Ultimate Frisbee on a high level. Richard, your passion for Ultimate Frisbee is just unreal. Besides being injured, you completely committed to the club, kept investing time in making people better and showed me not to give up in difficult times. Stidge, your fun competitive attitude such a unique approach I was blessed having experienced. Sharing the field with you was always the pure enjoyment and coaching together helped me develop more different approaches to coaching and leading a team.

The most memorable day in this period was that one day in June 2019 where Force Elektro became Dutch champion for the first time in the club history. I am not going to lie, as we all know the path was far from easy and we almost took a very wrong exit on the way. Nevertheless, we managed to grow together as a team and we showed what team spirit and determination could lead to: Dutch Ultimate Frisbee Champion 2019, Force Elektro. Thank you for sharing this great experience with me: Bert, Camilo, Dani, Georg, Guido, Jasper, Jos, Klaas, Lennart, Leo, Martijn, Max, Mika, Nathan, Patrick, Wouter. Thank you for trusting in me as your coach. I can tell this year I learned the most and it was an honour to be part of that team which defined itself by great team

spirit. FORCE ELEK---TROOOO!!! Thank you to all other Force Elektro members I had the chance to meet during my time in Delft! It was an amazing experience sharing a big part of my time with you!

Viki, thank you for being such an awesome listener. It always a great relief to talk to you about the challenges in- and outside the PhD life. I appreciate all the times you managed to visit, and I feel sorry not having been able to return that favour, yet. Tim and Tomasz, what adventures we have managed to experience. Thanks for the several kitesurfing sessions, the trip to the Sahara and the hike in Iceland with you guys was one of the best hikes in my life. I am certainly looking forward to other adventure trips with you to come. Benjamin, I admire your passion for both science and sports, very much similar how I try to make it the last four years. Thanks for teaching me a bit of biology in our collaboration, I really enjoyed working together with you. I hope we can catch up again for some tennis matches since it was a lot of fun despite me loosing most of the times. Karo, having you as a roommate was such a great time. Your kindness exceeds any scale, so much that it sometimes makes me wonder how a person can possibly that kind.

Claudi, Anne, Chrisi und Lukas, vielen Dank für die unzähligen Skype Sessions. Es war immer erfrischend mit euch in alten Erinnerungen unserer gemeinsamen Zeit in Erlangen zu schwelgen. Sebastian, vielen Dank für die Gastfreundschaft bei meinen Besuchen in Erlangen. Es ist immer wieder schön, an die alte Wirkungsstätte zurückkehren zu können und so herzlich willkommen geheißen zu werden.

Florian und Markus, unsere gemeinsamen Unternehmungen gaben mir immer ein Gefühl des nach Hausekommens. Vielen Dank für die gemeinsamen Bergtouren, Skiurlaube und Spielerunden. Aber am dankbarsten bin ich dafür, dass ich mich auf euch immer verlassen kann und in schwierigen Zeiten wir als Brüder immer zusammenhalten können.

Liebe Mama, lieber Papa, das Beste kommt zum Schluss. Worte zu finden, welchen Verdienst ihr an diesem Erfolg habt, ist fast unmöglich. Ich will es trotzdem versuchen: Oft gratuliert ihr mir für meine Errungenschaften, die ich unabhängig und ohne viel Hilfe erreicht hätte. Ihr habt selten Unrecht, aber in der Hinsicht muss ich euch energisch widersprechen. Alles was ich bis jetzt erreichen konnte, war nur mit eurer Hilfe möglich. Für die Unterstützung, die ich von euch erfahren durfte, über all die Jahre hinweg, in der Schule, and der Universität und während meiner Promotion bin ich euch auf ewig dankbar. Ihr habt immer versucht, mir alle Dinge zu ermöglichen und mir Arbeiten abzunehmen, damit ich mich besser auf die Schule/Uni/Promotion konzentrieren konnte und das ausüben konnte was mir Spaß macht. Ohne eure Hingabe und Unterstützung wäre es mir unmöglich gewesen, so weit in meiner akademischen Laufbahn zu kommen, die jetzt mit dem Dokortitel gekrönt werden wird. Vielen lieben Dank! Ich bin unendlich dankbar und stolz, euch als Eltern zu haben.

CURRICULUM VITAE

Dominik Benz was born on June 26, 1990 in Roth, Germany. He finished primary education in Obermaessing followed by completing high school in Hilpoltstein in 2010 where he started developing his interests in chemistry choosing this subject as part of his general higher education entrance qualification (Abitur). After serving his civil service in the army base Bogen, he committed 2011 to study Molecular Science at the Friedrich-Alexander University Erlangen-Nuremberg. He completed his BSc program in 2013 focusing on synthetic chemistry for water splitting catalysts and obtained his MSc degree in 2015. During his MSc studies, he was granted an exchange scholarship at the University of Wollongong, Australia, broadening his knowledge on polymer chemistry in the working group of Prof. Dr. Marc in het Panhuis. As his MSc thesis project, he choose to work on buffer layers for thin film solar cells by atomic layer deposition under the guidance of Prof. Dr. Julien Bachmann. In 2016 Dominik joined Prof. Dr. Ruud van Ommen's group in Chemical Engineering at Delft University of Technology to pursue his PhD degree. In the framework of Delft Global Initiative, he was working on the catalyst development by atomic layer deposition for cleaning water using sunlight. During his PhD studies he had the chance for a short research stay at Phenikaa University, Hanoi, Vietnam, to experience first-hand the severe water pollution in surface water.

Dominik took actively part in the Ultimate Frisbee community in Delft and in The Netherlands. Under his guidance as coach of the 1st men team Force Elektro became Dutch National Champion 2019 for the first time in club history. Additionally, he competed with the Dutch National team at the European Ultimate Championships in Győr, Hungary in 2019.
