# Samenvatting

Momenteel staat we voor grote uitdagingen, waaronder het aanpakken van klimaatverandering. Industriële processen die moeilijk te verduurzamen zijn, zoals staalproductie, (olie)raffinage en afvalverwerking, veroorzaken een aanzienlijke uitstoot van broeikasgassen. De reststromen van deze processen kunnen echter worden verwerkt met behulp van gasfermentatie, een recent ontwikkelde technologie. De kern van het gasfermentatie proces is de omzetting van synthesesgas, bestaande uit koolmonoxide CO, kooldioxide CO<sub>2</sub>, en waterstof H<sub>2</sub>, tot ethanol en azijnzuur door bacteriën zoals *Clostridium autoethanogenum*. Deze stoffen kunnen vervolgens dienen als grondstof voor nuttige producten zoals brandstoffen, plastics en cosmetica.

Hoewel gasfermentatie al wordt toegepast op industriële schaal, bestaan er onzekerheden over de opschaling van dit proces, met name omtrent de interacties van verschillende schalen binnen de bioreactor, bellen en bacteriën. Onder meer vertragen de lage oplosbaarheid van CO en H<sub>2</sub>, samen met het samenvloeien van bellen, de massaoverdracht van de gas- naar de vloeistoffase, gebruikelijkerwijs aangegeven middels een lage  $k_L a$ -waarde. Daarnaast verloopt de menging in grootschalige bioreactoren (500 m<sup>3</sup>), veel trager dan in kleinschalige lab-schaal bioreactoren (0,5 tot 2 L). Gecombineerd met een aanzienlijke gasomzetting leidt dit tot grote variaties in concentraties van opgelost gas. De concentratievariaties die bacteriën in de bioreactor ervaren, worden vaak gerelateerd aan onverwachte productiviteitsverliezen. Dit proefschrift onderzoekt

- i) de relevante factoren voor het verkrijgen van voldoende massaoverdracht op industriële schaal,
- ii) de omvang en duur van de concentratiefluctuaties en hun nabootsing op laboratoriumschaal, evenals
- iii) de mogelijke impact hiervan op *C. autoethanogenum*.

Deze kwesties worden uitgebreid geïntroduceerd in hoofdstuk 1.

In hoofdstuk 2 wordt de massaoverdracht in industriële gasfermentatiereactoren (gaslift bioreactoren met externe lus) nader bekeken. Empirische correlaties die vaak voor opschaling worden gebruikt, voorspelden te lage massaoverdrachtswaarden voor CO (0,3 tot 2 gL<sup>-1</sup> h<sup>-1</sup>), terwijl op industriële schaal 7 tot 8,5 gL<sup>-1</sup> h<sup>-1</sup> verwacht wordt. Met een numeriek model, dat de gas- en vloeistofstromen binnen een industriële bioreactor voorspelt, kon de invloed van relevante variabelen voor massaoverdracht, zoals de druk, de temperatuur, en de belddiameter, worden nagegaan. Hieruit bleek dat vooral kleine bellen (< 2 mm) nodig zijn om de benodigde waarden te behalen, wat deels te danken is aan het geproduceerde ethanol, die het samenvloeien van bellen vermindert.

Vervolgens wordt in hoofdstuk 3 experimenteel uitgezocht in welke mate ethanol en componenten van fermentatiebeslagen (zoutig kweekmedium en biomassa) het samen-vloeien van bellen verhinderen en de  $k_La$ -waarden verhogen. Uit deze experimenten bleek dat ethanol aanzienlijk bijdraagt aan het verkleinen van gasbellen (van 3 naar 1 mm), en de  $k_La$ -waarden 2 tot 6 keer kan verhogen. Ook het zout in het medium zorgt voor kleinere bellen. Het geproduceerde ethanol speelt een substantiële rol in het aanzienlijk verhogen van de massaoverdracht op industriële schaal. Bovendien werd vastgesteld dat de empirische correlaties, doorgaans ontwikkeld met metingen van lucht in gezuiverd water, onvoldoende rekening houden met de complexiteit van fermentatiebeslagen.

Met het ontwikkelde stromingsmodel wordt in hoofdstuk 4 de grootte en frequentie van de concentratiefluctuaties in grootschalige gasfermentatiereactoren in kaart gebracht. Dit gebeurt door massaoverdracht en gasconsumptie door bacteriën mee te nemen in het bioreactormodel, voor verschillende biomassaconcentraties. Hieruit bleek dat bacteriën, ongeacht de hoeveelheid biomassa in de reactor, concentratiefluctuaties ervaren van ongeveer één orde van grootte. De tijd die bacteriën doorbrengen in gebieden met hoge en lage concentraties is onregelmatig en varieert tussen de 5 en 30 seconden. Om de invloed van deze concentratiefluctuaties op *C. autoethanogenum* te onderzoeken, werd voorgesteld om een neerschakelingsstudie uit te voeren waarbij deze fluctuaties worden nagebootst in het laboratorium. Dit kan worden bereikt door onregelmatige variaties aan te brengen in de roersnelheid van een continu werkende bioreactor, met de eerder genoemde tijdsduur.

In hoofdstuk 5 is een eerste voorspelling gemaakt van het effect van de concentratiefluctuaties. Hiervoor werd een numeriek model van het metabolisme van *C. autoethanogenum*, wat de belangrijkste reacties binnenin de cel beschrijft, gekoppeld aan het stromings- en massaoverdrachtsmodel van de industriële bioreactor. Deze bevindingen zijn vergeleken met experimentele resultaten en beide lieten zien dat de opgeloste CO-concentratie een cruciale rol speelt bij de productie van azijnzuur of ethanol: een hoge CO-concentratie leidt tot azijnzuurproductie, terwijl een lage concentratie de ethanolproductie stimuleert. Bovendien werd er verwacht dat de concentratiefluctuaties ook zouden resulteren in een versterkte ethanolproductie.

Ter afsluiting worden de onderzoeksvragen uitvoerig beantwoord in hoofdstuk 6, en worden aanknopingspunten voor vervolgonderzoek uitgewerkt in hoofdstuk 7. Over het geheel genomen concluderen we dat het beschouwen van de interacties tussen de verschillende schalen (bioreactor, bellen en bacteriën) van essentieel belang is voor succesvolle opschaling van gasfermentatiebioreactoren. Meer onderzoek, waaronder bestudering van de gasopnamesnelheid van *C. autoethanogenum*, is vereist om dit proces nauwkeuriger te kunnen voorspellen.

Dit proefschrift biedt niet alleen nieuwe fundamentele inzichten in gasfermentatie, maar draagt ook bij aan verdere implementatie ervan in de industrie, waarmee het bijdraagt aan de strijd tegen klimaatverandering.

# Summary

One of the major challenges mankind faces nowadays is combating climate change. A substantial fraction of greenhouse gases are released by industrial processes, as steelmaking, (oil)refinery and waste processing. Emissions from these processes can partly be prevented with a recently developed technology called gas fermentation. Within this process, synthesis gas – a mixture containing CO, CO<sub>2</sub> and H<sub>2</sub> – is converted into ethanol and acetic acid by bacteria such as *Clostridium autoethanogenum*. These products could be used in a wide range of applications, like fuels, plastics and cosmetics.

Whilst gas fermentation is already applied at commercial-scale, challenges in scale-up persists due to complex multi-scale interactions among the bioreactor, gas bubbles, and bacteria. The poor solubility of CO and H<sub>2</sub> alongside gas bubble coalescence, leads to low gas-to-liquid mass transfer rates (typically denoted via  $k_L a$ ). Slow mixing in industrial bioreactors (500 m<sup>3</sup>), and high gas conversion rates, result in large spatial variations in dissolved gas concentrations. Bacteria experiencing concentration fluctuations have often been related to decreased process performance. This dissertation explores

- i) the relevant factors to obtain high mass transfer rates at industrial-scale,
- ii) the magnitude and duration of the concentration fluctuations, and how these can be resembled at laboratory-scale, and
- iii) the possible impact of these concentration fluctuations on *C. autoethanogenum*.

Chapter 1 serves as a comprehensive introduction into these themes.

Mass transfer in industrial-scale gas fermentation reactors (primarily external-loop gas-lift bioreactors) is extensively studied in Chapter 2. The engineering correlations that are often used for bioreactor scale-up, predicted insufficient CO mass transfer capacities (0.3 – 2 gL<sup>-1</sup> h<sup>-1</sup>), while at scale 7 – 8.5 gL<sup>-1</sup> h<sup>-1</sup> is expected. With a computational fluid dynamics (CFD) model of an industrial-scale gas-lift bioreactor, the influence of the most relevant variables regarding mass transfer, i.e., pressure, temperature, and bubble diameter, have been studied. The model revealed that predominantly small bubbles (< 2 mm) are required to obtain the industrial-scale performance. The produced ethanol was expected to inhibit coalescence, facilitating the creation of such small bubbles.

Chapter 3 focuses on experimental investigations regarding the impact of ethanol and broth components (mineral medium and biomass) on bubble coalescence and  $k_L a$  enhancement. The findings indicated that ethanol substantially reduces the gas bubble diameter (from 3 to 1 mm) and thereby amplifies  $k_L a$  between 2 to 6 times. The salts in the medium demonstrated a similar effect in reducing bubble size. The study emphasises the key role of ethanol in achieving industrial-scale mass transfer rates, and highlighted

that the engineering correlations, which were mostly developed in air-water mixtures, are not suitable to describe the complex interactions within fermentation broths.

The CFD model is expanded in Chapter 4 to explore the magnitude and duration of the concentration fluctuations that the bacteria experience in the large-scale bioreactor. This was done by modelling mass transfer and gas consumption for a wide range of biomass concentrations. Irrespective of the biomass concentration, bacteria experienced concentration fluctuations of approximately one order of magnitude. The duration in concentration peaks and valleys varied irregularly, spanning between 5 and 30 seconds. To assess the impact of such concentration variations on *C. autoethanogenum*, a downscaling study was proposed to simulate these fluctuations at laboratory-scale gas fermentation conditions. It was proposed to irregularly modulate the stirring speed of a continuously operated bioreactor for periods of the aforementioned duration.

An initial evaluation of the impact of the concentration fluctuations is made in Chapter 5. This was done by coupling a metabolic kinetic model of *C. autoethanogenum* to the CFD and mass transfer model of the industrial-scale bioreactor. Comparison of simulation results with experimental data, uncovered that the dissolved CO concentration influences the product spectrum: elevated dissolved CO concentrations favours acetic acid production, while ethanol production is stimulated at lower concentrations. The simulations suggested that the concentration fluctuations led to escalated ethanol production rates at the expense of acetic acid production.

In Chapter 6, the research questions will extensively be answered, while future research suggestions will be elaborated in Chapter 7. Ultimately, this dissertation concludes that accounting for multi-scale interactions – amongst bioreactor, bubbles and bacteria – is crucial for successful scale-up of gas fermentation bioreactors. Further research, including investigation of gas uptake kinetics of *C. autoethanogenum*, is required to refine the accuracy of gas fermentation modelling.

This dissertation provides novel fundamental insights into gas fermentation field, it also contributes to furthering its implementation in the industry, thereby contributing to the fight against climate change.

NADPH	Nicotinamide adenine dinucleotide phosphate
O <sub>2</sub>	Oxygen

# Chapter 1

## Introduction

*The implementation of biotechnology, in terms of process scale-up and operation, would not have been possible without application of mathematical concepts and methods which lie at the heart of modern engineering and education.*

James Edward Bailey [1]

---

This chapter has been written to provide the reader background information for each chapter. Each chapter contains its own introduction.

**B**iototechnology is fundamental to our society. Humanity has mastered the act of using microorganisms for multiple purposes: from cleaning our wastewater to brewing beer, from cultivating food to generating fuels and plastics, even to save lives by producing pharmaceuticals and preventing pandemics using vaccines. The miraculous microbial world enables us to solve many of the urgent challenges society faces: from preventing food shortages to mitigating climate change, to changing our meat industry. One of the solutions the microbial world offers us is called *gas fermentation*.

## 1.1. The potential of gas fermentation

In the late 1980's, early 1990's, microorganisms were discovered that were able to use synthesis gas (syngas), a gas mixture containing carbon monoxide (CO), hydrogen (H<sub>2</sub>) and carbon dioxide (CO<sub>2</sub>), as carbon and electron sources to produce useful products as ethanol and acetate [2, 3]. The workhorses of this process, acetogenic bacteria like *Clostridium ljungdahlii* and *C. autoethanogenum*, were isolated shortly afterwards from chicken yard waste and rabbit feces [4, 5]. Since the late 2000's, research into this technology has skyrocketed, with tens of research articles and many<sup>1</sup> review papers being published every year [6].

The potential of the gas fermentation process is founded in its versatility: syngas can be produced from a wide range of feedstocks, while also a wide range of products can be produced (Figure 1.1). The products range from acetate and ethanol, to longer chain carboxylic acids and alcohols [7], proteins and precursors for polymers [8], while the production of acetone and isopropanol have been demonstrated at pilot-scale [9]. Current commercial applications convert industrial off-gases towards ethanol, which can be upgraded to a wide range of products like car fuel, plastics (as polyethylene), detergents, clothing, and cosmetics [8–11].

Syngas has been used in the chemical industry for many years. With fossil carbon as input, it has mainly been used in Fisher-Tropsch Synthesis for hydrocarbon production and in catalytic conversion to methanol [12, 13]. In some industries, such as the steel-making and the ferroalloy industry, syngas is typically considered as a waste stream and only used for energy generation. By fermentation these fossil-based waste streams can be valorised [14]. Potential circular processes can be obtained by gasification of waste streams such as lignocellulosic biomass residues and municipal solid waste [15]. Lastly, efforts are being made to use atmospheric CO<sub>2</sub> and green hydrogen as feedstocks for the syngas fermentation process, using CO<sub>2</sub> and/or water electrolysis [11].

Compared to the catalytic (e.g., Fisher-Tropsch and syngas-to-methanol) processes for syngas conversion, the biological process offers several advantages [11, 13–15]: *i*) operation at ambient temperatures and pressure (saving energy costs), *ii*) microbes are

<sup>1</sup>Too many, according to the authors opinion: around 22% (93 out of 425 hits) of the Web of Science article collection on “syngas fermentation” published between 2019 and 2023 has been marked as a review paper, while other areas average around 10% (dated October 23<sup>rd</sup> 2023).

Figure 1.1: Schematic representation of the syngas fermentation process, feedstocks and end-products.

cheap catalysts and offer high resistance to contaminants (sulfur, tars), *iii*) no fixed ratio between CO and H<sub>2</sub> is required, and *iv*) higher specificity and carbon-to-product yields can be obtained. However, biological processes take place in water, leading to low volumetric productivity (or space-time-yield) although productivity per gram biomass and catalyst are similar [13], and the low product concentration challenges product separation [16]. These advantages offer syngas fermentation the potential to become more attractive and environmental-friendly than the competing chemical processes for the production of fuels from syngas.

Figure 1.1 schematically illustrates the syngas fermentation process. After production of the syngas, the gas is being compressed and cleaned to remove impurities such as tars, nitrogen oxides and sulphates [17, 18]. The separation and purification of ethanol after fermentation is commonly done via distillation and pressure swing absorption, although more efficient and sustainable downstream processes have been proposed [16].

## 1.2. Commercialisation of gas fermentation

As was recently demonstrated with their initial public offering, the company LanzaTech successfully scaled-up the syngas fermentation process. They were founded in 2005 in New Zealand, and opened their first full-scale plant in 2018 in Shougang, China, where they produce ~50 kton ethanol per year using off-gases from a neighbouring steel-mill (Figure 1.2a). Currently, LanzaTech is expanding its operations and building facilities across the world, amongst others in India, South-Africa, and in Ghent, Belgium, in the Steelanol project with ArcelorMittal (Figure 1.2b) [10].

Figure 1.2: Photographs of industrial-scale syngas fermentation plants, depicting LanzaTech's external-loop gas-lift reactors. a) Shougang-LanzaTech plant near Beijing, China<sup>2</sup>, b) Steelanol plant near Ghent, Belgium, the author is visible for scale.

At scale, the syngas fermentation process is performed in an external-loop gas-lift reactor (EL-GLR) (see Figure 1.1 for a schematic and Figure 1.2 for photographs of their industrial-scale EL-GLRs). Based on these photographs, the reactor is approximately 30 metre tall and 5 to 7 m wide, and encompasses a volume of more than 500 m<sup>3</sup> [10]. This reactor is similar to the well-known bubble column, but it contains an external-loop to force (a part of) the liquid back to the bottom, where pressurised gas is injected. Due to its density difference with the fermentation broth (the liquid mixture containing water, biomass and the liquid products), the gas and, consequentially, the broth rise upwards, which is recirculated via an external-loop aside of the reactor [19, 20]. The external-loop can be used, amongst others, for cooling, liquid feeding and withdrawal, while a (multiphase) pump can be installed to regulate the mixing time (and mass transfer). LanzaTech claims an ethanol specificity of 95% [8], near-complete gas conversion (~90%) [10], and an ethanol concentration of 50 gL<sup>-1</sup> [8] (similar to beer).

Compared to other bioreactor types that are used in commercial-scale processes (mainly stirred tank reactors), the EL-GLR offers low capital and operational costs (no stirring required) and decent mixing characteristics [14, 15, 21]. Other reactors that are frequently studied (at lab-scale) for gas fermentations include hollow fibre membrane reactors (with limitations like clogging) [21–23] and trickle bed bioreactors (with low working volumes and flow rates) [21, 23], which both require biofilm formation.

### 1.3. Concerns on gas fermentation scale-up

In the scientific literature, there are many concerns on the scalability of the gas fermentation process and the EL-GLR. These relate to gas-to-liquid mass transfer, biomass and product concentrations, and the existence of dissolved gas concentration gradients. As will be shown here, all these issues relate to the interactions between the operational parameters of the bioreactor, the physical phenomena in the EL-GLR (such as mass transfer and mixing) and the microorganisms and their metabolism. In this work, these concerns will be studied, while aiming to find solutions to overcome or alleviate these.

#### Mass transfer

Transport of the syngas components from the gas phase to the liquid phase, gas-to-liquid mass transfer, is often regarded as the major limitation in syngas fermentation due to the low solubility of CO and H<sub>2</sub> [2, 13–15, 17, 22]. The mass transfer rate depends on a mass transfer coefficient  $k_L$ , the gas fraction  $\varepsilon_G$ , the bubble diameter  $d_b$  (both combined into the volume-specific surface area  $a$  of the gas phase), and the solubility of the compound. This large number of parameters means that the mass transfer rate is influenced by many different factors, such as the broth composition, the pressure  $p$ , the temperature  $T$ , and the local turbulent energy dissipation rate  $\epsilon$  [24–26].

The standard engineering correlations for bubble column and gas-lift bioreactors, could not predict the high mass transfer performance of industrial-scale EL-GLRs. For example, as a rule of thumb in columns with coarse bubbles, an oxygen depletion rate of 0.55% per metre liquid height can be assumed [26]. Translating this to a 30 m tall syngas fermentor, this would maximally lead to 16.5% CO conversion, significantly lower than the 90% advocated by LanzaTech. To achieve this 90%, a depletion rate of at least 3% per metre is needed, which could for example be in columns with very small bubbles [26]. As gas sources can be costly, high gas conversion rates and thus high mass transfer rates are paramount design parameters for competitive gas-based bioprocesses at scale (e.g., using syngas, oxygen, methane, H<sub>2</sub>, and CO<sub>2</sub> [27–30]).

#### Productivity

Another major hurdle in syngas fermentation experiments is the low volumetric productivity (or: space-time yield), which can be attributed to the low microbial growth rate  $\mu$  [13, 17, 22]. Typically, a low  $\mu$  leads to low biomass concentrations  $c_x$  and thus low product concentrations  $c_{\text{prod}}$ . Biomass retention has been identified as a tool to increase the volume-specific ethanol productivity and gas conversion rates [22, 31].

High biomass concentrations might cause significant mass transfer limitations, and therefore thermodynamically unfavourably low concentrations of dissolved gases [32]. In contrast, a too low  $c_x$  could increase the dissolved gas concentrations so much that CO becomes inhibiting [33, 34]. This results into a narrow operational window, governed by the mass transfer rate and the biomass concentration. Furthermore, high ethanol

concentrations could inhibit growth and product formation [35, 36], but might also lead to increased mass transfer rates by decreasing  $d_b$  [37].

Within the scientific community, there is some variability in understanding of the gas fermentation product spectrum. So far, usually acetate is regarded as the main acetogenic gas fermentation product [38–40], and it is unclear at which conditions high ethanol specificity prevail, although several influential factors have been identified. For example, low pH [38], high (extracellular) acetate concentrations [31, 39, 41], addition of nitrate [42], and specific medium optimisation [43] could enhance the ethanol production rates. Increased ethanol production rates were obtained in chemostats by increasing the biomass concentration [44], by increasing the dilution rate [45], or by  $H_2$  supplementation [45, 46]. 2,3-butanediol and lactate can be considered as by-products due to their low product concentrations (1:10 ethanol) [47]. It should be noted, however, that the conducted chemostat lab-studies with CO as main electron source never reached the 90% specificity as is obtained in industry with CO-rich syngas.

## Concentration gradients

In industrial-scale continuous or fed-batch bioreactors, spatial gradients in substrate (e.g., glucose,  $O_2$  or CO) concentration are frequently observed. They typically arise due to poor mixing in the liquid phase and too slow mass transfer from the gas phase [48, 49]: When mass transfer or mixing are slower than consumption of the gas, then such gradients are likely to occur [50]. As mixing in lab-scale ( $\sim 2$  L) is usually much faster, these gradients are usually identified at industrial-scale ( $\sim 500\,000$  L). As most industrial microorganisms were characterised at lab-scale, and the scaled-up performance was typically estimated from the lab-scale performance, these concentration gradients got associated with significant performance losses [51–53]. Studying how these concentration gradients influence the microbial metabolism (i.e., all the reactions that occur within the cell [54]) is therefore paramount for successful scale-up.

In large-scale reactors for syngas fermentations, the existence of a spatial dissolved gas concentration gradient is expected due to the varying hydrostatic pressure, bubble size, gas fraction and gas composition [32, 55, 56]. From *lifeline* analysis (i.e., the concentration variations from the perspective of the microorganism [57, 58]) decreased product yields and growth rates were expected based on analogy with *E. coli* [56] in a modelling study. Currently, there is no (experimental or modelling) information on how the metabolism of acetogens is affected by the environmental fluctuations, and thus how these would influence gas uptake and the product spectrum.

## Scaling-up by scaling-down

The existence of concentration gradients has often been related to (unexpected) performance losses after scale-up [52], with as consequence that successful bioreactor scale-up has often been regarded as "both art and science" [59–61].

One successful scale-up strategy is the “begin with the end in mind”-concept [62, 63]. This implies that lab-scale experiments should consider the industrial environment from the perspective of the cell. By mimicking the industrial conditions in a so-called scale-down simulator, the microbial response to these conditions (i.e., temperature, product concentration, pH, but most importantly, the relevant concentration gradients) can be assessed [64, 65]. This should, first of all, lead to less surprises while scaling-up but it can also enable the selection of more resilient microbial strains and the development of metabolic models [66, 67]. In the scientific literature, no scale-down experiments have been done for syngas fermentation. Such experiments could determine whether decreased yields (as mentioned above) would occur and how the cellular metabolism would respond in terms of product spectrum.

Bioreactor modelling has been proven as a viable tool to design scale-down experiments from the cellular perspective [64, 66, 68]. Despite several drawbacks of modelling, it is the best alternative as long as large-scale data is unavailable [69].

## 1.4. The craftsmanship of fermentation modelling

*All models are wrong, but some are useful* - George Box [70]

Every model is a representation of reality, and it is therefore possible to decide on the level of reality representation. Typically, implementing more physical and (bio)chemical phenomena increase the model accuracy, at the cost of the model complexity and simulation time, whereas the model could also be simpler and faster by neglecting more phenomena, and thus limiting the model resolution and accuracy. In fermentation modelling, one has to decide on simulation purpose (what is its use?), the level of accuracy (which phenomena should be included?) and resource requirement (how many CPU hours can we spend, or how long can we wait?). As such personal choices have to be made during fermentation model development, fermentation modelling should be regarded as a *craft*.

Fermentation models typically contain sets of balances (of mass, chemical species, energy and/or momentum) for various phases (gas, liquid, biomass), with transport and source terms for inter-phase transport and reaction. To solve these balances, assumptions have to be made on the physical description of the bioreactor and of the microorganism. Models for gas fermentation bioreactors (e.g., the EL-GLR), have to cover a wide range of multi-scale phenomena: One should consider the interrelationships between geometry and operational conditions (e.g., pressure and temperature, gas inflow) of the bioreactor (at the metre-scale), mass transport from the gas to the broth via the bubbles (at the millimetre-scale), and gas consumption and product formation by the microorganisms (at the micrometre-scale). The interactions between phenomena at all these different scales are visually represented in Figure 1.3.

In this section, the various types of models typically used for modelling bioreactors and microorganisms will be discussed.

## Models for bioreactors

The reactor model with the lowest amount of complexity is the zero-dimensional *ideal-mixing* model. The bioreactor is assumed to be well-mixed, thereby neglecting the existence of concentration gradients [71]. These models can be complemented by engineering relations for predicting phenomena such as the gas hold-up, bubble diameter, and the mass transfer rate more accurately [19, 25, 26]. For continuous (chemostat) bioreactors, these models are typically solved in a *steady-state* situation, wherein equilibrium is obtained between the in- and outgoing streams. Models that consider variations over time (e.g., how is the equilibrium obtained?) are referred to as *dynamic* models and could also be used to simulate full batch and fed-batch bioprocesses.

More details can be acquired using one-dimensional convection-dispersion models, which could predict how variables (e.g., the gas hold-up, mass transfer rate and dissolved gas concentrations) would vary along height and time, and have often been applied in bubble column and gas-lift modelling [72–74]. The advantage of these models is that they are fast: They can be used to estimate liquid and gas flow rates and the resulting concentration gradients, and allow coupling to detailed metabolic models [75]. Since these models are only 1D, they do not describe the turbulence inside the bioreactor, nor lack the fundamental equations to predict a detailed gas and liquid flow pattern inside the reactor, which is partly responsible for both mass transfer and the concentration gradient.

In contrast, *Computational Fluid Dynamics* (CFD) models can be used to obtain a high-resolution flow field in the bioreactor. By dividing the reactor into small volume-elements (a mesh) the equations for continuity (mass balance), momentum (Navier-Stokes), turbulence and chemical species transport can be solved. There are many different models for solving multiphase flow behaviour; the Volume of Fluid model (for separated or stratified flows), the mixture model (approximating multiphase flow patterns by solving only a single momentum equation describing the mixture), and Eulerian models where separate momentum equations are solved for each phase. A seemingly large variation of models is available for turbulence modelling. Of these, the RANS  $k - \epsilon$  (Reynolds-Averaged Navier-Stokes) model is currently the workhorse for CFD modelling in large-scale bioreactors, although the more detailed LES (Large Eddy Simulation) models are gaining popularity [76]. The most detailed model is the DNS (Direct Numerical Simulation) model, wherein the Navier-Stokes equations are solved explicitly in each volume element [77].

Environmental dynamics from the cellular perspective can be studied by releasing virtual, Lagrangian, particles that follow the liquid flow in the bioreactor. These particles can represent (a package of) individual cells. By coupling the Lagrangian particles with the Eulerian model, the environmental fluctuations (in for example dissolved gas concentration) can be recorded, resulting into a lifeline. This Euler-Lagrangian model allows us to record the history of the microbe, while potentially considering the intracellular state by coupling a metabolic model [58, 78].

Practical details concerning the modelling setup are provided in later chapters. For an extensive overview of the equations and underlying model assumptions in CFD modelling, the interested reader is referred to [77, 79], while for gas-liquid interactions (such as drag, lift, bubble-induced turbulence, and turbulent dispersion), choices have to be made dependent on the physical phenomena in the system [80–82].

## Models for microorganisms

A *black-box* model is the simplest model to describe microorganisms. This model assumes simultaneous import of substrates and product export, using a process reaction, that can be based on experimentally derived yields, or based on thermodynamics [83, 84]. The major disadvantage of black-box modelling is that it is unclear what happens inside the microbe as mechanisms for carbon and electron storage are not included. This hampers its applicability for predicting the influence of the dissolved gas concentration gradients on the microbe and its metabolism. One step further is the inclusion of cell maintenance and growth using the Herbert-Pirt relation [85], wherein substrate uptake can be related to the substrate concentration using a kinetic equation, with special emphasis to the one developed by Monod [86], while still assuming an instant equilibrium between the intra- and extracellular environment.

To predict the metabolic fluxes, genome-scale metabolic models (GEMs) of *C. autoethanogenum* have been constructed [87, 88], and applied to chemostat reactors for syngas fermentation [45, 46, 89, 90]. Such models are reconstructed from genome information, and can be supplemented with experimental data or with an objective and a set of constraints (Flux Balance Analysis, FBA), to predict intracellular as well as import and export fluxes, while assuming a metabolic steady-state [54]. One should note that the selection of the constraints and objective (which could be maximum growth or minimum uptake) is challenging and condition-specific. Due to the assumption of metabolic steady-state the applicability of FBA in a dynamic environment is weak, although dynamic FBA approaches have been suggested that couple FBA outputs to a dynamic extracellular environment [91]. GEMs usually contain hundreds to thousands of reactions, making model solving expensive and hamper its ability to couple it with CFD.

In between the black-box and the GEMs are so-called (pooled) kinetic metabolic models [40, 92–94]. These models do not consider the entire genome or metabolism but focus on a smaller reaction network, possibly by lumping several metabolic reactions and/or metabolites into pools. The models are called *Cellular Reaction Dynamics* (CRD) models, as they are able to predict the metabolic dynamics in time scales from seconds to days [94]. They are also called structured metabolic models, while the black-box description is said to be unstructured [1, 95]. These CRD models can be solved by integrating a more limited set of differential equations, making it possible to couple it with CFD [78] using the Lagrangian particle model, and elucidate the impact of substrate gradients on the metabolism, and on the reactor performance as a whole.

Figure 1.3: Schematic overview of the interactions between operational parameters, the physics in bubble column-type bioreactors, and microorganisms. The complexity of the hydrodynamics in the bioreactor is provided on the left, while the various biological modelling approaches are provided at the right part of the scheme. The key elements regarding the microbial experience, at various scales, are provided in the middle part of the scheme. The operational parameters are provided at the left side, outside of the graph.

Population balance modelling has been done to describe population heterogeneity. For example, such a model was used to describe the variations in  $\mu$  among a cell population in a bioreactor [96], and has been coupled to a  $\mu$ -dependent intracellular model at various scales [97]. Although these models can be used to predict variations in one or two states, they cannot be used to gather intracellular details as in CFD-CRD modelling [66].

The first CFD-CRD coupling was published in the noteworthy works of Lapin et al. [58, 98], and was applied later on to industrial-scale fermentations [99, 100]. Since then, many reviews and perspective papers have exemplified the use of this method [63, 66, 67, 101, 102], but the actual execution seems to be challenging given the lack of actual research output using this method. The challenge probably arises due to the complexity of CFD modelling, and difficulties on developing trustworthy kinetic pool models.

## 1.5. Thesis scope and outline

The liquid phase concentrations of the dissolved gases, biomass and products are at centre of the complex multi-scale interrelationships in bioreactors. Figure 1.3 clearly shows them at the intersection between the reactor physics and the microorganism, depicting that they are fundamental parameters for bioprocess performance and scale-up.

This work explores the multi-scale interactions between bioreactor, bubbles and bacteria in the context of gas fermentation and how these should be addressed for scale-up, considering the concerns raised in Section 1.3 (i.e., low mass transfer rates, low (ethanol) productivity, the dissolved gas concentration gradient and the lack of scale-down studies). This will be done in a step-by-step fashion, by gradually zooming in (and sometimes out) on an industrial-scale EL-GLR, while aiming to answer the following questions in the end:

- What are the factors that should be considered to achieve sufficient mass transfer rates for successful operation of a commercial-scale gas fermentation process?
- What is an effective way to represent industrial-scale gas fermentation conditions at bench-scale?
- What is the influence of the dissolved gas concentration and its gradient on the metabolism and product spectrum of *C. autoethanogenum*?

The common engineering correlations used to describe gas-to-liquid mass transfer [25], significantly underpredicted the required mass transfer rate for commercial-scale operation (see Appendix 7.6, Table 2.1), highlighting the scientific concern regarding mass transfer in gas fermentation scale-up. The factors that could induce sufficient mass transfer in an industrial-scale EL-GLR will be investigated in **Chapter 2**. This will be done by developing and validating a CFD model which could describe the gas and liquid flow inside a pilot-scale external-loop airlift bioreactor. This model will then be applied in the

large-scale EL-GLR and used to test strategies to obtain commercial-scale mass transfer performance.

In **Chapter 3**, the identified strategies (or: hypotheses) from Chapter 2 to obtain high mass transfer rates in the EL-GLR will be tested in a lab-scale bubble column. First, the influence of the produced ethanol and its concentration on the bubble size distribution and the  $k_L a$  will be studied. Next to this, the fermentation medium (containing salts and vitamins) and the whole broth (containing biomass) will be studied. By determining the physical properties of each mixture (surface tension  $\sigma$ , viscosity  $\eta$  and density  $\rho$ ) the accuracy of the empirical mass transfer correlations will be assessed.

After understanding how high mass transfer rates could be obtained, it will be studied how the biomass concentration relates to gas uptake rates (and thus productivity) and the dissolved gas concentration gradient in **Chapter 4**. This will be done by implementing a mass transfer model and a Monod-type, black-box, kinetic model for CO and H<sub>2</sub>-uptake in *C. autoethanogenum* in the CFD framework developed in Chapter 3. From Euler-Lagrangian simulations, a scale-down simulator will be proposed to replicate the industrial-scale environment at lab-scale. The developed scale-down simulator should enable experimentalists to study the influence of the dissolved gas concentration gradient on cellular metabolism.

The impact of the dissolved gas concentration and its gradient on the cellular metabolism and the product spectrum will be investigated in **Chapter 5**. Here, a metabolic kinetic model of *C. autoethanogenum* will be coupled to the CFD model developed in the previous chapters. This will enable a full coupling between the phenomena in the bioreactor and the metabolism (see Figure 1.3). It will be studied how high ethanol production rates may be obtained and how that is influenced by multi-scale (from hydrodynamic to enzymatic) phenomena.

After wrapping up our results in **Chapter 6**, the research questions will be answered. Perspectives towards future work will be provided in **Chapter 7**.

Please keep seated for an amazing journey from bioreactors to bubbles to bacteria, across the wonderful world of gas fermentation!

## Hydrodynamics and mass transfer in external-loop gas-lift reactors

*Perfect is the enemy of good*

Voltaire

---

This chapter has been published as:

Puiman, L., Abrahamson, B., Van der Lans, R. G. J. M., Haringa, C., Noorman, H. J., & Picioreanu, C. (2022). Alleviating mass transfer limitations in industrial external-loop syngas-to-ethanol fermentation. *Chemical Engineering Science*, 259, 117770.

## Abstract

Mass transfer limitations in syngas fermentation processes are mostly attributed to poor solubility of CO and H<sub>2</sub> in water. Despite these assumed limitations, a syngas fermentation process has recently been commercialised. Using large-scale external-loop gas-lift reactors (EL-GLR), CO-rich off-gases are converted into ethanol, with high mass transfer performance ( $7 - 8.5 \text{ g L}^{-1} \text{ h}^{-1}$ ). However, when applying established mass transfer correlations, a much poorer performance is predicted ( $0.3 - 2.7 \text{ g L}^{-1} \text{ h}^{-1}$ ). We developed a CFD model, validated on pilot-scale data, to provide detailed insights on hydrodynamics and mass transfer in a large-scale EL-GLR. As produced ethanol could increase gas hold-up (+30%) and decrease the bubble diameter ( $< 2 \text{ mm}$ ) compared to air-water mixtures, we found with our model that a high volumetric mass transfer coefficient ( $650 - 750 \text{ h}^{-1}$ ) and mass transfer capacity ( $7.5 - 8 \text{ g L}^{-1} \text{ h}^{-1}$ ) for CO are feasible. Thus, the typical mass transfer limitations encountered in air-water systems can be alleviated in the syngas-to-ethanol fermentation process.

## Graphical abstract

## 2.1. Introduction

The conversion of waste gases by synthesis gas (syngas) fermentation has advanced to industrial scale in the last decade. In this process, a gas mixture containing CO, CO<sub>2</sub> and H<sub>2</sub> can be converted by microbes (predominantly *Clostridium* spp.) into a range of chemicals, e.g., acetic acid, ethanol, acetone and isopropanol [103]. The company LanzaTech has been able to commercialise the process of converting CO-rich off-gases from steel-mills into ethanol. Currently they deploy ethanol production facilities in China, while expanding their manufacturing network to other countries [8, 10, 103].

Details of the full-scale operation are unknown in the scientific literature due to the proprietary nature of this process. It is expected that syngas conversion takes place in a gas-lift reactor with an external circulation loop [104]. This reactor configuration, also known as the external loop gas-lift reactor (EL-GLR) is like a conventional air-lift loop reactor as applied in waste-water treatment and industrial bioprocesses. Compared to the more established bubble column reactors (BCRs), in external-loop airlift reactors (EL-ALRs) there is forced liquid recirculation (potentially but not necessarily via pump action) through the downcomer (the external-loop), causing high liquid velocities, a more defined (plug) flow pattern and a shorter mixing time [20, 105]. The external-loop might also be used for heat exchange, introduction of fresh feed and broth withdrawal [106].

The increased liquid velocity in the riser is known to decrease the gas residence time and thus the gas hold-up ( $\varepsilon_G$ ) and the volumetric mass transfer coefficient ( $k_L a$ ) compared to a bubble column [107, 108]. At the same time, gas-liquid mass transfer is generally known to be one of the limiting factors in syngas fermentation processes [2, 22, 23, 109, 110]. For industrial ethanol production, it was determined that a  $k_L a$  of at least 580 h<sup>-1</sup> should be reached for commercial success [111]. Our preliminary calculations, based on publicly available data reported by LanzaTech, show that a mass transfer capacity ( $MTC$ ) of 7–8.5 g L<sup>-1</sup> h<sup>-1</sup> should be reached, which results in a  $k_L a$  between 600 and 750 h<sup>-1</sup>, based on a headspace pressure of 1 bar and 50% CO in the inlet gas (Figure A.1).

For estimation of  $k_L a$  in air-water systems, many relationships have been provided in the literature for different reactor types [25]. With these relations the most likely  $k_L a$  was estimated at industrial conditions and compared to the  $k_L a$  from our preliminary calculations (Table 2.1), resulting into a  $MTC$  between 0.3 and 2.7 g L<sup>-1</sup> h<sup>-1</sup>. A clear discrepancy between the  $k_L a$  obtained by these relations and the supposed industrial performance was found, as all engineering correlations predict a substantially lower  $k_L a$ . Although it is widely known that electrolytes, organic molecules (such as the produced ethanol), biomass, and the reactor geometry influence  $k_L a$  [25, 26], the impact of these factors are not comprehensively considered with the correlations in Table 2.1. Furthermore, empirical relations obtained for ALRs were derived at smaller scales and their validity for larger scales bears uncertainties. The non-standard reactor geometry and irregular flow pattern in industrial reactors complicate the prediction of the mass transfer per-

**Table 2.1:** Relationships used for the prediction of  $k_L a$  in Newtonian media in a large-scale EL-GLR, as well as typical  $k_L a$  values for industrial operation. See Tables A.1 and A.2 for the meaning, units and calculation of variables in these equations. The empirical correlations were developed for air-water systems, and would require a small correction (around 5% lower) for CO due to its lower diffusion coefficient compared to oxygen [113].

formance using common correlations, which are normally valid for a narrow range of conditions and were derived in shorter columns (influencing  $u_{G,s}$ ) while assuming ideal mixing. Spatio-temporal variations complicate the *a priori* estimation of  $\varepsilon_G$ ,  $k_L a$  and  $MTC$  as particular geometry configurations strongly influence the hydrodynamics in ALRs (e.g., riser width/height, separator dimensions and the particular connection of the downcomer). For example, while the liquid and gas velocities are expected to be high in the riser, these should decrease in the wider separator section in the top of the vessels and consequently increase the local  $\varepsilon_G$  [112].

Several models have been developed to describe hydrodynamics of pilot- and full-scale airlift bioreactors. The model by Van der Lans [74] predicted the axial mean values of liquid circulation velocity and gas fraction in a pilot-scale external-loop bioreactor well. Van Benthum et al. [124] modelled three-phase hydrodynamics (liquid velocity, gas and solid hold-up) in a biofilm airlift suspension extension reactor, wherein the liquid velocity in a gas-free downcomer is controlled independently from the gas flow velocity. While neglecting spatial variations of gas, liquid and solids concentrations in the internal

regions, the model was well able to predict the pilot-scale hydrodynamics. Earlier, Heijnen et al. [125] described the liquid circulation velocity and gas hold-up in an industrial-scale biofilm internal-loop airlift suspension reactor, based on mass and momentum balances. This model is applicable to three hydrodynamic regimes: gas-free downcomer (regime 1), entrained gas in downcomer (regime 2) and gas back-circulation via downcomer (regime 3). We argue that in the LanzaTech case, operation in regime 1 or 2 may be preferred compared to regime 3 as the latter could reduce the CO partial pressure and thus its saturation concentration in the riser.

Convection-dispersion and tanks-in-series (1D) models have been proposed to understand mixing and mass transfer phenomena in small-scale airlift reactors [126], but it is unclear how the flow pattern deviates from these simple mixing models for the large-scale EL-GLR. It is generally known that large-scale BCRs show high axial dispersion coefficients [26] but that EL-ALRs studied at lab and pilot-scale display more plug-flow behaviour [108]. As the axial dispersion behaviour is unclear in an industrial EL-GLR, the convection-dispersion models turned out to be unsuitable for the prediction of the large-scale flow pattern and gas-liquid mass transfer rates. Furthermore, several relations have been developed to describe the mass transfer coefficient  $k_L$ , based on local conditions such as the slip velocity and the eddy dissipation rate (Table 2.2). These relations require a high spatial resolution, which cannot be provided by the 0D and 1D models.

With 3D computational fluid dynamics (CFD) models a high spatio-temporal resolution can be obtained, albeit with a much greater computational effort than when applying simple mixing models. For EL-ALRs, several authors used CFD to study the hydrodynamics and the mixing behaviour [133–135]. Hydrodynamics and oxygen mass transfer in a lab-scale sectionalized EL-ALR has been studied recently; it was demonstrated that the  $k_L a$  predicted with Equation 2.5 (Table 2.2) matched the experimental data better than predictions from Equation 2.1 and 2.3 [136]. Similar work was done earlier, wherein it was

observed that Equation 2.3 showed a strikingly good agreement with experimental results [137]. Most of these models were developed for lab and pilot-scale EL-ALRs, with riser diameters smaller than 0.14 m, where wall effects can be significant [105].

A CFD model for syngas fermentation in a BCR with a population balance model for the gas phase was developed recently [56]. Low  $k_La$  values and thus low CO transfer rates, low dissolved CO concentrations and low CO uptake rates were obtained as more than 50% of the bubbles had a relatively high bubble diameter ( $d_b > 8$  mm). Several one-dimensional models have been presented for syngas fermentation in large-scale BCRs as well. de Medeiros et al. [138] developed such a model for the optimisation of different process conditions. They determined that strategies needed to be obtained to enhance the  $k_La$  with at least a factor three, relative to air-water correlations, to decrease the minimum ethanol selling price to \$0.7/L and reach high (70%) thermodynamic efficiency. Another BCR model was coupled with a black-box stoichiometric model for *C. autoethanogenum* based on thermodynamics in order to estimate the ethanol productivity in such a reactor. High productivities were obtained  $4.25 \text{ g}_{\text{EtOH}} \text{ L}^{-1} \text{ h}^{-1}$ , but this was at the expense of the gas utilisation (only 17%) as high gas flow rates were used [32]. In another 1D model, with kinetics reported by LanzaTech, a genome-scale metabolic model for a proprietary *C. autoethanogenum* strain was coupled to bubble column hydrodynamics. In their model  $k_La$  and microbial CO uptake rate varied axially between 350 and  $425 \text{ h}^{-1}$  and 0 and  $7 \text{ g L}^{-1} \text{ h}^{-1}$ , respectively, by assuming  $d_b$  below 1.5 mm and constant  $k_L$  of  $1 \times 10^{-4} \text{ ms}^{-1}$  [55]. However, detailed analyses how the low  $d_b$  and high  $MTC$  could be accomplished in industrial reactors are lacking.

Thus far, no CFD model has been developed for describing the hydrodynamics and CO mass transfer in a large-scale external-loop gas-lift reactor, for studying the required conditions to minimise the gas-liquid mass transfer limitations in an industrial syngas fermentation process. Next to that, the results of such a model would provide information to be used for subsequent reactor design and optimisation. The model that we have developed in this study for hydrodynamics and mass transfer in an EL-ALR was first tested and validated by comparing local axial gas and liquid flow velocities in the riser and the downcomer, gas hold-up, and turbulence intensity with pilot-scale results obtained by Young et al. [139]. Then, using the same model equations, the large-scale EL-GLR hydrodynamics and gas transfer were simulated and compared with correlations and observations from literature. For varying bubble diameters (between 1 and 7 mm), higher temperatures and gas hold-up, and a range of headspace pressures,  $k_La$  and  $MTC$  were determined using different relations (Table 2.2), in order to establish the best operation window for high industrial performance.

## 2.2. Methods

### Reactor geometry and mesh

In this work, two reactor geometries were considered: A pilot-scale geometry to compare CFD model predictions with experimental results and a full-scale reactor for the subsequent mass transfer study. The hydrodynamic CFD model was applied to data obtained by Young et al. [139] for a pilot-scale external-loop reactor (2.95 m high, riser and downcomer diameter of 19 and 14 cm, 260 L reactor volume, 160 L liquid volume). This reactor configuration was chosen as it was found that the gas hold-up was independent of the riser diameter when wider than 14 cm [105]. The 3D geometry was developed using ANSYS Design Modeller. A polyhedral mesh (400000 cells, 0.27 minimum orthogonal quality) with a higher resolution in the dispersed-phase domain was developed in ANSYS Meshing (Figure A.2).

The dimensions of the industrial-scale reactor were estimated from openly available pictures of the Shougang-LanzaTech plant (Figure 1.2), and are schematically represented in Figure 2.1. The 3D geometry has been developed using cylindrical bodies, with a ring sparger [139] mounted at 0.1 m above the reactor base. The total volume of the reactor equals 840 m<sup>3</sup>, with an ungassed liquid volume of 565 m<sup>3</sup>, which roughly corresponds to the 500 m<sup>3</sup> volume presented by LanzaTech [10]. A mesh with 370,000 polyhedral cells, 0.3 minimum orthogonal quality, 20 cm cell size and three refined boundary layers near all walls (including sparger), was constructed in Fluent Meshing. A mesh refinement study done using meshes with 1.6 and 1.9 million cells established that the 370,000-cell mesh was sufficient for determining  $k_L a$  and  $MTC$  within 10% accuracy (Figure A.2, Table A.3).

### Fluid dynamic model

The transient gas-liquid flow was computed within ANSYS Fluent 2020R1 with the Eulerian multiphase flow model, with implicit volume fraction formulation, dispersed RNG  $k-\epsilon$  turbulence model, which is the recommended choice for bubble column modelling [140], and standard wall functions. The forces involved in the two-phase interaction were surface tension (continuum surface force), drag (Fluent's universal-drag model) and gravity. A model with a similar set of forces was used before for syngas fermentation modelling in BCRs [56].

In the pilot-scale ALR, mean air bubble diameters ranged from 4 to 6 mm [139], therefore as dispersed phase 5 mm bubbles were modelled. For the large-scale reactor, the mean bubble diameter is unknown and could range between 1 and 7 mm, based on the liquid properties and operating conditions [26]. Because coalescence inhibition can be expected due to the salt and ethanol-rich fermentation broth, 3 mm bubbles were modelled in the large-scale hydrodynamic model, according to [141], by assuming a sparger orifice size of 0.75 mm.

A mass-flow inlet was used on the sparger surface at the bottom of the reactor, providing a fixed mass flow rate of gas (Table 2.3). A pressure-outlet with gas backflow was

## Mass transfer model

The mass transfer studies in the large-scale bioreactor were performed after a statistically stationary ("steady") flow field was established (after 1000 seconds simulation time, using 3 mm bubbles). For an additional 200 s, dynamic flow data was exported every second for time-averaging and processed in Tecplot 360 EX 2018 R1. Based on the computed flow field,  $k_L a$  and  $MTC$  were calculated via six different relations for  $k_L$  (Table 2.1). Spherical bubbles were assumed because of the small bubble diameter and bubble-stabilizing effects of dissolved solutes (Equation 2.7) as well as a linear gradient in axial gas phase CO mole fraction  $y_{\text{CO}}$  (considering 90% CO conversion (Figure A.1)) (Equation 2.8). The

Table 2.5: Parameters used for mass transfer calculations.

Symbol	Description	20 °C	37 °C	Unit	Source
$\nu_L$	Kinematic viscosity	$1.018 \times 10^{-6}$	$7.121 \times 10^{-7}$	$\text{m}^2 \text{s}^{-1}$	Reid et al. [142]
$D_{L,\text{CO}}$	CO diffusion coefficient	$1.78 \times 10^{-9}$	$2.71 \times 10^{-9}$	$\text{m}^2 \text{s}^{-1}$	Cussler [143]
$H_{\text{CO}}$	Henry coefficient	$2.93 \times 10^{-7}$	$2.29 \times 10^{-7}$	$\text{kg m}^{-3} \text{Pa}^{-1}$	Sander [144]

impact of the bubble size was studied in the 1 – 7 mm range. The influence of the operating temperature was considered as it affects the liquid viscosity, CO diffusion coefficient and Henry constant (Table 2.5). For the calculation of  $MTC$ , microbial CO uptake kinetics are not required, instead a dissolved CO concentration of  $0 \text{ gL}^{-1}$  was assumed in all grid cells.

$$MTC = k_L a \cdot c_{L,\text{CO}}^{\text{sat}} = k_L \cdot \frac{6\varepsilon_G}{d_b \varepsilon_L} \cdot H_{\text{CO}} p y_{\text{CO}} \quad (2.7)$$

$$y_{\text{CO}}(z) = -\frac{(y_{\text{CO},\text{in}} - 0.9 y_{\text{CO},\text{in}})}{h_D} z + y_{\text{CO},\text{in}} \quad (2.8)$$

## Model solution

The transient models were solved using ANSYS Fluent 2020R1. For the pilot-scale models, a time step of 0.01 s was used with a maximum of 30 iterations per time step, wherein the residuals decreased to  $O(10^{-3})$ . The results presented here were obtained by storing flow data at the positions mentioned by Young et al. [139] every 0.01 s, starting at 50 s (when a steady flow field was reached) until 110 s flow time.

For the industrial reactor, the time step  $dt$  was gradually increased from an initial 0.01 s until 0.65 s,  $dt = 0.025$  s until 3 s,  $dt = 0.05$  s until 5 s and  $dt = 0.1$  s from 5 seconds on. This time-stepping strategy was required to keep solution convergence (residuals  $< O(10^{-3})$ ) within 10 – 25 iterations per time step, and found to be crucial to achieving convergence near the mesh-refined sparger location. The solution methods, spatial discretization and relaxation factors for both reactor models are given in Table A.4.

## 2.3. Results and discussion

In this section, the flow pattern predicted by the CFD model will first be compared with the pilot-scale data obtained by Young et al. [139] (section 2.3.1). After this, the results at the large-scale are discussed (section 2.3.2) in terms of the gas hold-up, flow pattern and hydrodynamic regime. Then, results on mass transfer and strategies for relieving the gas-liquid mass transfer limitations will be discussed (section 2.3.3), before we sketch the implications of this research in the outlook (section 2.3.4).

### 2.3.1. Pilot-scale flow pattern

The computed liquid velocity in the riser was compared with the velocity profiles along the radius obtained experimentally by Young et al. [139] (Figure 2.2). The computed mean liquid velocity in the riser approximates the measured one with maximum deviations of 36% (Table A.5). However, the computed velocity gradients along the column radius were consistently smaller (i.e., flatter velocity profiles) than those measured (i.e., showing usually a sharp maximum at the axis at  $r/R = 0$ ). The radial profiles of the turbulence intensities in both the riser and downcomer are quite similar to the data, but the model underestimates the turbulence intensity in the riser, while overestimating in the downcomer. This is probably a result of the simplified set of forces considered in the model. Roy et al. [135] were able to model the radial liquid velocity profile by using the standard  $k-\epsilon$  model and taking the turbulence dispersion and lift forces into account, together with a conveniently chosen bubble size. On the other hand, liquid velocity measurement errors up to 10% for the riser were noted from a liquid phase mass balance by Young et al. [139], which could possibly explain part of the deviation between model and measurements. The (gas-free) downcomer velocity profile, however, showed good correspondence, as well as the profiles predicted for the gas hold-up and gas velocity. The trends for increasing superficial gas velocities were modelled correctly for all variables.

By simulated injection of a liquid tracer (with the same properties as water) just above the sparger, it was determined that the model can predict the typical circulating liquid mixing behaviour as often shown in airlift reactors [105, 145]. The tracer concentration profile over time  $c_t$  extracted from the CFD simulations was normalised with the final (steady state) concentration  $c_{t,\infty}$ . This normalised tracer concentration over time  $t$  was fitted with Equation 2.9 [105] expressing the fluctuations of concentration over a normalised time  $\theta$  ( $\theta = t/t_c$ , with  $t_c$  the circulation time), as function of the Bodenstein number ( $Bo = u_{L,ax}L_c/D_{ax}$  with  $L_c$  the circulation length and the axial dispersion coefficient  $D_{ax}$ ).

$$\frac{c_t}{c_{t,\infty}} = \left( \frac{Bo}{4\pi\theta} \right)^{1/2} \sum_{n=1}^{\infty} \exp \left[ \frac{-(n-\theta)^2 Bo}{4\theta} \right] \quad (2.9)$$

In this way,  $Bo$  and  $t_c$  for the EL-ALR were determined at several locations in the reactor (Figure 2.3). The model predicted  $Bo$  values around 45, which are typical estimations for  $Bo$  in an ALR [146, 147], indicating the dominance of the plug-flow in the

**Figure 2.2:** Comparison of radial profiles obtained by experiments in a pilot-scale EL-ALR [139] (filled circles) and mean values of CFD results (open circles with dashed lines) for different  $u_{G,s}$  (8.4 (blue), 4.7 (black), 2.1 (red) and  $0.96 \text{ cm s}^{-1}$  (cyan)). a) the axial liquid velocity in the riser ( $u_{L,ax}$ ), b) the axial liquid velocity in the downcomer ( $-u_{L,ax}$ ), c) the axial gas velocity in the riser ( $u_{G,ax}$ ), d) the turbulence intensity in the liquid in the riser and e) downcomer, and f) the gas hold-up in the riser. Error bars: the standard deviation of the CFD results during 60 s simulation time (data stored every 0.01 s).

reactor. A mean circulation time of about 7.6 s resulted from the tracer model with a  $u_{G,s}$  of  $8.4 \text{ cm s}^{-1}$ .

Considering that most of the flow parameters were determined to be within a 25% range of experimental values (Table A.5) and the good correspondence with mixing theory, we considered the model appropriate for engineering calculations. Furthermore, the most important variable concerning mass transfer, the gas hold-up, was reasonably well predicted. In order to be sure that the radial liquid velocity profile is properly predicted, it will be compared with theoretical predictions for this profile in large-scale EL-ALRs in the upcoming section.

**Figure 2.3:** The normalised concentration of a tracer obtained from the CFD model (black lines) and concentration according to the axial dispersion model for ALR (Equation 2.9) (red lines), compared at four locations in the pilot-scale reactor. For all locations, the Bodenstein number was  $\sim 45$  with the root-mean-square-error (RMSE) smaller than 0.1. The CFD data has been obtained at  $u_{G,s}$  of  $8.4 \text{ cm s}^{-1}$ .

### 2.3.2. Large-scale flow pattern

In this section, the results of the large-scale reactor CFD model are presented. First, its ability to predict the gas fraction is discussed, since this is a key variable regarding mass transfer. Then the gas and liquid velocity-fields are analysed in detail. Lastly, the radial profiles of the liquid velocity in the riser and the observed time-variations are discussed.

The simulated gas hold-up in the EL-GLR was on average 0.13 at a superficial gas velocity of  $2.8 \text{ cm s}^{-1}$ . This value was in good agreement with the values obtained from several correlations available in literature for BCRs and EL-ALRs (Table 2.6).

The local values of the instantaneous gas hold-up (Figure 2.4a) were averaged in time over 200 seconds (Figure 2.4c). The CFD simulations indicate that at the bottom of the reactor, the freshly sparged gas is strongly pushed towards the wall of the riser, which might result in bubble coalescence, by the liquid exiting the downcomer. This is also visible in the liquid flow patterns (Figure 2.4b, d). When the gas is pushed towards the left side, the local liquid velocity increases, creating a circulation loop around the downcomer outlet. Similar behaviour has been observed experimentally for bottom-plate spargers

**Table 2.6:** The 200 s time- and volume-averaged gas hold-up  $\epsilon_G$  determined by CFD in the EL-GLR, riser and downcomer, compared with values from established correlations. The values of  $u_{G,s,r}$  and  $u_{L,s,r}$  used in the correlations were the averages of the time-averaged axial superficial velocities computed in six horizontal planes across the riser. 1:  $v_b^\infty = 0.25 \text{ m s}^{-1}$ , 2:  $L_{\text{con}} = 0.5 \text{ m}$  and  $L_d = 19.5 \text{ m}$ . Other parameters in Table A.1.

Bello et al. [114]	EL-ALR	$\epsilon_G = 0.16 \left( \frac{u_{G,s,r}}{u_{L,s,r}} \right)^{0.56} \left( 1 + \frac{A_d}{A_r} \right)^{-1}$	0.149
Choi and Lee [149] <sup>2</sup>	EL-ALR	$\epsilon_{G,r} = 0.288 u_{G,s,r}^{0.504} \left( \frac{A_d}{A_r} \right)^{-0.098} \left( \frac{L_{\text{con}}}{L_d} \right)^{-0.094}$	0.112

[105] and also from CFD models developed for different EL-ALRs [135].

Halfway the riser the instantaneous gas hold-up shows an asymmetric distribution (Figure 2.4a), while the time-averaged gas hold-up (Figure 2.4c) is more symmetrical with high values along the riser axis, indicating an oscillating gas plume. This is also apparent from the velocity plots, with liquid moving back and forth between the sides (Figure 2.4b). Such oscillating behaviour has been observed experimentally in internal-loop airlift reactors [150]. However, by time-averaging these movements cancelled-out and a quasi-symmetric velocity profile was obtained (Figure 2.4d). While the liquid mostly rises, the negative values observed near the riser wall indicate a certain degree of back-mixing, which has also been observed experimentally in ALRs [20, 151]. This internal liquid recirculation contributes to the overall mixing in the riser and creates axial and radial dispersion.

Approaching the gas-liquid separator at the top of the riser, the gas hold-up tends to increase as gas expansion (decreasing hydrostatic pressure) and the wider separator diameter (decreasing the local liquid velocity) increase the gas residence time. This particular section of the reactor could become advantageous for mass transfer because the expected lower CO saturation concentration (due to the lower hydrostatic pressure and a lower CO fraction in the gas) can be compensated by the increase in gas hold-up.

Just above and in the downcomer inlet, high  $\varepsilon_G$  as well as high liquid flow velocities were predicted. While the liquid flow is directed horizontally and downwards, the bubbles dragged into the downcomer will rise. This causes a sharp separation between gas and liquid and consequently high  $\varepsilon_G$ . Similar behaviour was found by modelling EL-ALRs with comparable geometry [133, 134, 137]. Degassing geometries might prevent the gas to flow into the downcomer [152]. At the left side of the downcomer, the drag by the liquid and buoyancy of the gas bubbles are in equilibrium and therefore a stable gas hold-up is obtained over time (Figure 2.4c). This corresponds to the second gas entrainment regime [125], wherein the gas bubbles entrained in the downcomer do not reach the bottom and only partially fill the downcomer. Higher local gas hold-up in the downcomer close to the riser wall was also observed in internal-loop airlift reactors [153].

The question emerges on how high the recirculation through the downcomer is in the EL-GLR compared with the internal recirculation in the riser. From the velocity field it was determined that, in this particular reactor geometry, about 14% of the liquid goes down via the downcomer while the rest flows downwards near the riser walls. This indicates that axial mixing in the riser is significant and plug-flow behaviour cannot be assumed for the liquid phase. Although the downcomer appears to be poorly used for the liquid circulation in the studied operation regime, it clearly increases the liquid flow rates in the riser compared to a bubble column (with zero net axial liquid velocity). Such results highlight the added value of CFD predictions as this behaviour could not be predicted with simpler 1D models.

Figure 2.4: Surface plots in the  $yz$ -plane ( $x = 0$ ) of the EL-GLR ( $u_{G,s} = 0.028 \text{ m s}^{-1}$ ). a), b) gas hold-up and liquid velocity magnitude at a certain moment in time after establishing the flow field ( $t = 1100$  s), with arrows indicating the velocity vectors. c), d) gas hold-up and axial liquid velocity averaged over 200 s.

**Figure 2.5:** Radial profiles for the axial liquid velocity in the EL-GLR (with  $u_{G,s} = 0.028 \text{ m s}^{-1}$ ). Open circles: 200 s time-averaged mean velocities; error bars: time-variations observed via the standard deviation; dashed lines: parabolic profile calculated with Equation 2.10.

In the pilot-scale model, a parabolic velocity profile was not observed (Figure 2.2) therefore the large-scale model needed to simulate local axial and radial velocity variations. At several heights in the riser, the profile of axial liquid velocity along the whole riser diameter was calculated over time, then compared with a parabolic profile (Equation 2.10, Figure 2.5) characteristic for BCRs and ALRs [154]. Both parameters of the parabolic profiles, velocity at the riser axis  $u_{L,ax}(r = 0)$  and superficial liquid velocity  $u_{L,s,ax}$ , were taken from time-averaged CFD results.

$$u_{L,ax}(r) = (u_{L,ax}(r = 0) - u_{L,s,ax}) \left( 1 - 2 \left( \frac{r}{R} \right)^2 \right) + u_{L,s,ax} \quad (2.10)$$

At the lower locations (5.1 m and 7.4 m) the liquid velocity profile is skewed towards the left side, due to the liquid entering from the downcomer. However, the liquid velocity profile shifts towards the central axis at higher locations in the riser, where it matches the proposed parabolic profile. It should be noted that there are large time-variations, which should be taken into account when analysing mass transfer in EL-GLRs, for example by time-averaging for 200 s (Figure A.3).

Many phenomena found at pilot-scale were also predicted by the simulations to occur in the large-scale external-loop reactor. Moreover, the predicted overall gas hold-up and liquid flow velocities showed a good match with literature relations. From all these indicators it can be concluded that with a CFD model the large-scale hydrodynamic behaviour can be described properly. With this hydrodynamic model, subsequent calculations on  $k_L a$  and  $MTC$  will be performed and are discussed in the next section.

### 2.3.3. Mass transfer

Gas fermentation processes are developed towards a multitude of products, e.g., acids, alcohols, ketones, glycols, aromatics, dienes, esters and terpenes [8]. Although the literature is very scarce on their influence on mass transfer in fermentation broths, it is known that hydrophilic products inhibit bubble coalescence in water, thereby decreasing the Sauter mean bubble diameter ( $d_{32}$ ) [37], and increasing  $k_L a$  [155]. In a pilot-scale bubble column (3 m high, 20 cm width), Keitel and Onken [37] found decreases in  $d_{32}$  from 4 to 1 mm and doubling of  $\varepsilon_G$  from 2 to 4%, for a variety of alcohols. By increasing hydrophobic chain length, stronger effects (i.e., occurring at lower concentrations) were reported, for  $d_{32}$ ,  $\varepsilon_G$ , and  $k_L a$  [37, 155]. Similar results (<1 mm bubbles and highly increased  $\varepsilon_G$ ) in tall bubble columns were obtained with ethanol [156–159], while Krishna et al. [160] found that the ethanol stabilises the homogeneous flow regime (i.e., bubbly flow at higher  $u_{G,s}$ ).

In ALRs, however, organics increased  $\varepsilon_G$  up to a modest 30% [161, 162]. The smaller influence of organics on  $\varepsilon_G$  in ALRs compared to BCRs was explained by, amongst others, the higher velocities of the axial liquid flow [107]. The expected ethanol concentration in the LanzaTech reactor (50 g L<sup>-1</sup>) [111] is much higher than the minimum concentrations for coalescence inhibition (1 – 10 g L<sup>-1</sup>) [37]. Therefore, we can assume a low  $d_{32}$  (optimistic scenario: about 1 mm; pessimistic scenario: 3 mm) in the scenario with ethanol, whereas scale-independent  $d_{32}$  between 5 and 7 mm are observed in BCRs with air-water mixtures [25, 26, 163]. Likewise, it may be assumed that the produced ethanol could increase the local gas hold-up by at least 30% compared to solutions without ethanol.

Furthermore, temperature dependencies of the physical properties show a significant influence on the mass transfer. By operating at a temperature of 37°C,  $k_L a$  is estimated to be around 1.44 times higher than at 20°C [26], mainly due to an increased CO diffusion coefficient (+150%) and decreased liquid kinematic viscosity (-45%). However, the effect of this elevated temperature will be counteracted by a lower CO solubility through its Henry coefficient (-28%), which in turn negatively influences  $MTC$ . The net effect of a higher temperature, however, will still be positive.

Thus, for different models describing  $k_L$  (Table 2.1), the impact of the bubble diameter (varied between 1 and 7 mm) and the mutual impact of increased hold-up and temperature were examined (Figure 2.6). It was found that with a bubble diameter of 3 mm, most correlations predicted  $k_L a$  and  $MTC$  lower than those required by the process (Figure A.1), even with an increased hold-up and temperature. However, with 2 mm bubbles, sufficient  $k_L a$  and  $MTC$  were predicted using the relations from Higbie [127] and Kaštánek [129]. In addition, when including hold-up and temperature effects with 2 mm bubbles, also the relations from Calderbank and Moo-Young [128] and Linek et al. [130] led to adequate  $k_L a$  and  $MTC$ . If the bubble diameter would be 5 to 7 mm, which is expected for air-water mixtures in industrial BCRs [25, 26], then all correlations predict insufficient  $k_L a$  and  $MTC$ , causing mass transfer limitations. These values correspond with the values from Table 2.1, stressing the validity of these relations in air-water dispersions.

**Figure 2.6:**  $k_L a$  (a, b) and mass transfer capacity  $MTC$  (c, d), calculated using different  $k_L$ -relations (1 to 6 in Table 2.2) for varying bubble diameters, while considering the effect of produced ethanol on the gas hold-up and the higher temperature (b, d). Red: Higbie [127], cyan: Calderbank and Moo-Young [128], green: Kašánek [129], blue: Linek et al. [130], magenta: Lamont and Scott [131], black: Kawase and Moo-Young [132]. Error bars: standard deviation during a 200 s period with statistically stationary flow field; Black dashed line: lower value of the estimated range of the industrial process.

From this sensitivity analysis we can conclude that industrial-scale syngas fermentation in the EL-GLR requires small bubble diameters ( $\leq 2$  mm), which should be obtained in combination with a high gas hold up at 37°C. Ethanol presence promotes these conditions, while in air-water conditions (5 to 7 mm bubbles) the mass transfer limitations would not be alleviated. Therefore, our results indicate that in an industrial syngas fermentation process towards bubble-stabilising products, e.g., ethanol, the typical mass transfer limitations that are present in air-water systems can significantly be alleviated.

It is noted that there are large differences among the  $k_L a$  values predicted using the different  $k_L$ -relations. The relations based on eddy energy dissipation rate (2.3–2.6) predict lower values than the bubble-based relations (2.1, 2.2). The deviations with relations 2.1 and 2.2 could be due to underestimation of  $\varepsilon$  by the  $k$ - $\varepsilon$  turbulence model

[164]. Accounting for this with a scaling factor, based on the overall minimum power input [165, 166], would result in a 22% increase in  $k_L a$ . Moreover, it has been noted that relation 2.3 has a too high proportionality constant [132] compared to the similar relations 2.4–2.6. Generally, sensitivity analyses with different  $k_L$ -relations should be done in future modelling work on gas-liquid mass transfer. Experiments in EL-ALRs could determine which relation describes  $k_L$  the best in the specific reactor and how the produced ethanol and the higher temperature would influence the  $k_L a$ .

In some cases the  $k_L a$  was predicted to be sufficient, while the  $MTC$  was not (e.g., relations 2.5 and 2.6). This indicates that the ideal-mixing assumption (Figure A.1) may not hold and, instead, the *local* values of  $k_L a$  and solubility should be taken into consideration when computing  $MTC$ . Although high  $k_L a$  values were obtained at certain locations (such as in the separator), the contribution of these volumes to the overall mass transfer rate was found to be low because of the decreased CO saturation concentration (Figure 2.7). However, the high  $k_L a$  at the reactor top could be beneficial for CO depletion such that the off-gas only contains residual amounts of CO. As LanzaTech patented a method with the aim of, amongst others, increasing mass transfer in the headspace via a so-called ‘showerhead’ [104], it is expected that these local high  $k_L a$  values at the top of the reactor are indeed required for maximising gas conversion. Although significant CO mass transfer was predicted in the downcomer, when microbial consumption takes place, only marginal transfer is expected as the relative volume of the downcomer is small and as the EL-GLR is operated in the second hydrodynamic regime.

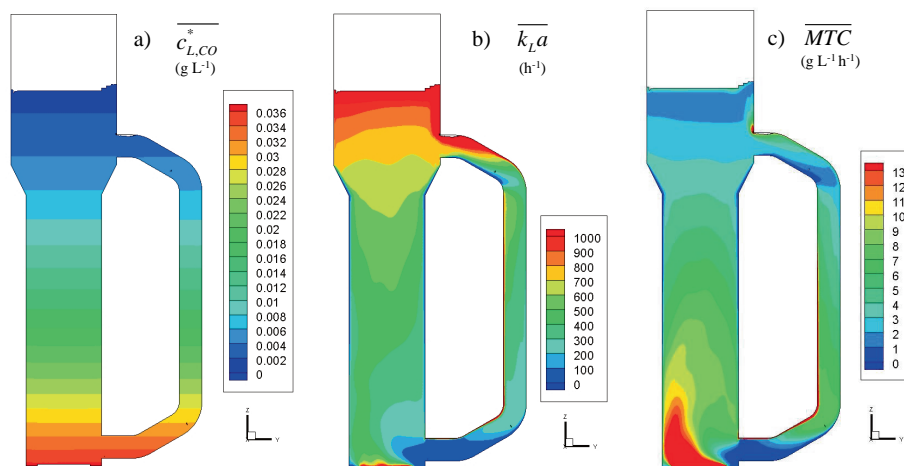

Figure 2.7: Surface plots on the  $yz$ -plane of the EL-GLR ( $x = 0$ ), showing 200 s time-averaged values for a) the CO saturation concentration in the liquid, b) the  $k_L a$  as predicted using the Higbie relation (Equation 2.1, c) the mass transfer capacity, assuming  $d_b$  of 3 mm, a 30% increase in gas-hold up compared to water due to the presence of ethanol and a temperature of 37°C.

**Figure 2.8:** Volume-averaged values of a)  $k_L a$  and b)  $MTC$  in the EL-GLR for different headspace pressures, calculated via different  $k_L$ -relationships (Table 2.2) assuming  $d_b$  of 3 mm, a 30% increase in gas-hold up compared to water due to the presence of ethanol and a temperature of 37°C. Red: Higbie [127], blue: Calderbank and Moo-Young [128], magenta: Lamont and Scott [131]. Bars: standard deviation during a 200 s period with statistically stationary flow field.

High pressure fermentation has been mentioned as a promising strategy to increase the mass transfer rate of poorly soluble gases [113]. Patents indicate that in lab experiments with higher operating pressures (304 and 608 kPa) increased ethanol titre and productivity was obtained [167, 168]. However, in the scientific literature, no beneficial effect was found on the productivity, while *C. ljungdahlii*'s product spectrum shifted from acetate and ethanol towards formate at increased pressures [169]. Inhibitory effects were observed for CO with an inhibition constant of 60 kPa [34], so that increased pressures could decrease the CO consumption rate. The gas saturation concentration increases proportionally with the pressure (Equation 2.7), but the gas hold-up would decrease (ideal gas law) with a constant gas (mass) flow rate. In order to study these opposing phenomena, the effect of increasing the headspace pressure on the  $k_L a$  and  $MTC$  was investigated by running CFD simulations with 304 and 608 kPa headspace pressure.

It was observed that increased headspace pressures decrease the  $k_L a$  significantly (Figure 2.8). This is due to the decrease in  $\varepsilon_G$ , which decreased from 0.13 to 0.054 and 0.033, at 304 and 608 kPa respectively. Similar values of  $MTC$  at increased pressure were observed when it was calculated using the relations of Higbie [127] and Calderbank and Moo-Young [128], while a slight decrease was observed with the eddy-based equation. Thus, the decrease in  $\varepsilon_G$  was neutralised by the solubility-increase. One should note that the compressor power requirement [113] increases sharply for increased pressures.

At elevated pressures, one could increase the gas mass flow rate linearly with pressure to obtain a constant superficial gas velocity and thus  $k_L a$ , without changing the hydrodynamic regime. In our study, the mass flow rate was assumed constant at  $2.11 \text{ kg s}^{-1}$ , causing decreasing superficial gas velocities and hold-up at elevated pressured. As is

it is expected that LanzaTech operates six reactors to produce in total  $48 \text{ kton a}^{-1}$  ethanol (Figure A.1), a higher gas mass flow rate at higher pressures was not likely. If the gas flow rate would be increased proportionally with pressure (to obtain constant  $k_L a$ ), a near-linear relationship between  $MTC$  and the compressor power requirement is obtained (Figure A.4), making operating at overpressures an economical choice. Moreover, considering CO-uptake kinetics, with high affinity and inhibiting effect at high dissolved CO concentrations [138], we would not recommend operation at higher pressures.

### 2.3.4. Outlook

The hydrodynamics and gas-liquid mass transfer in an industrial-scale reactor for the conversion of CO-rich steel-mill off-gases by syngas fermentation were studied by computational fluid dynamics. Simulation results indicated that conditions could be reached for industrially-sufficient specific mass transfer rates ( $k_L a$ ) and mass transfer capacities ( $MTC$ ). High  $MTC$  was found possible when the operating temperature is  $37^\circ\text{C}$  and by producing ethanol, which inhibits bubble coalescence to maintain relatively small bubbles ( $d_b \leq 2 \text{ mm}$ ), and increases riser gas hold-up ( $\sim 30\%$ ). We recognise that other factors (e.g., particular medium components or process engineering strategies) might also be deployed to obtain such mass transfer capacities. Since most of the  $k_L a$  relations from literature (Table 2.1) were derived in air-water systems, without considering any enhancing effects, further research is needed on the development of mass transfer correlations representing real fermentation conditions. Especially, these relations should consider the presence of bubble-stabilising compounds such as ethanol, acetone, and acetic acid, as well as the presence of salts, antifoam agents and microbial biomass. The addition of fine particles (e.g., kieselguhr, silica) can also increase  $k_L a$  substantially [170], possibly by minimising bubble coalescence [171], and could be included in such relations, which are pertinent for the development of more realistic CFD and process models.

The two-phase flow pattern in the large-scale reactor was found to be very dynamic, with large variations in the movement of the gas plume. As the local values of the gas solubility and  $k_L a$  determine  $MTC$ , the high spatio-temporal resolution that can be obtained via CFD was necessary for predicting the reactor performance and for determination of the main factors influencing mass transfer. Since the main limitation of CFD is its high computational demand, further research should focus on the development of coarse-grained computational models (such as compartment models) to determine  $k_L a$  and  $MTC$  in a faster way and as function of several variables such as the gas flow rate, media composition (enhancement agents), pressure and reactor scale and geometry.

The strong dynamics of the computed flow patterns in the large-scale reactor will determine the trajectories of microorganisms performing the syngas conversion. Consequently, the microorganisms would experience peaks and valleys in dissolved CO concentrations in an irregular fashion. By implementing CO-uptake kinetics, CO concentration profiles can be obtained for the different operating conditions. Euler-Lagrangian

simulations can then reveal what conditions microbes experience over time (*lifelines*) and how that would influence their (dynamic) behaviour [58]. Coupling the flow field with a metabolic model of *C. autoethanogenum* could reveal the influence of these dynamic conditions on the bioprocess performance and (by)product spectrum and guide the development of scale-down simulators and optimised reactor geometries [99].

To develop an optimal bioreactor, spatial homogenization of mass transfer is imperative [111], requiring high  $k_L a$  in zones with lower solubility (e.g., separator section) and low  $k_L a$  in zones with high solubility (e.g., lower riser section). Controlling the liquid flow rate in the riser, which determines the riser gas hold-up, could be done to fine-tune the local mass transfer capacity. Reducing the liquid backmixing could for example be accomplished by adding internal surfaces, such as perforated plates [20], which would additionally promote local bubble-break up [136], or by increasing the resistance in the downcomer [107, 172] by decreasing its diameter or adding a pump, to force the flow at the optimal rate. By decreasing the liquid flow rate in the riser, the riser gas hold-up can be increased, possibly leading to an increased mass transfer capacity. As this may increase the mixing time [146], one should balance the impact of the mass transfer time with the liquid mixing time when designing large-scale EL-GLRs. Using the downcomer, the liquid velocity and thus the gas velocity and hold-up can be adjusted, which cannot be done in a bubble column. The downcomer can also be used for product removal towards the distillation section, inflow of fresh medium or nutrients, heat transfer, and as source for supplying the showerhead [104].

Alternatively, by positioning the sparger above the downcomer inlet, the gas flow could be better distributed in the riser [105]. In this case, less bubble coalescence is expected as the gas is less likely to be pushed towards the wall opposite to the downcomer. Although the CO solubility is larger in the riser bottom, the higher sparger position would lead to a CO-depleted zone below the sparger, which decreases the overall mass transfer capacity. CFD simulations with a sparger above the downcomer inlet confirm a 4-6% decrease in *MTC*, due to the low gas hold-up below the sparger (Figure A.5, Table A.6). Further research on the sparger position and how the downcomer (and its position) influence bubble coalescence in ethanol-rich media could be helpful for designing industrial-scale EL-GLRs with higher productivity.

In this study, all the CO transferred to the liquid phase was assumed to be instantaneously consumed by the microbes. In practice, there will be CO dissolved in the liquid phase, thus decreasing the driving force for mass transfer. The dissolved CO concentration is determined not only by the local flow conditions and mass transfer rates, but also by the local microbial CO uptake rate, governed by the uptake kinetics (especially the affinity). The literature is very scarce on studies of CO uptake kinetics by *Clostridia* (e.g., [34]). Detailed CO uptake kinetics using dissolved CO concentration measurements should be developed with priority.

Many authors [2, 22, 110] explain the low mass transfer capacity obtained in syngas fermentation partly by the low solubility of CO. Solubility can also be affected by the ethanol fraction in the solution, and this effect has been mostly studied for O<sub>2</sub> dissolution. Shchukarev and Tolmacheva [173] determined little impact of ethanol on the O<sub>2</sub> solubility in the water-ethanol mixture for ethanol mole fractions below 0.2. Therefore, it is not expected that the CO solubility would be affected by the produced ethanol in the studied reactor conditions (50 g L<sup>-1</sup> ethanol or mole fraction ~0.02 [111]). Since O<sub>2</sub> and CO have comparable Henry coefficients at 37°C ( $9.6 \times 10^{-6}$  and  $8.2 \times 10^{-6}$  mol m<sup>-3</sup> Pa<sup>-1</sup>, respectively [144] and the CO fraction in syngas is often higher than the O<sub>2</sub> fraction in air, we argue that the challenges that have to be addressed in aeration processes should be faced in syngas fermentation as well. Instead of attributing the poor performance to the solubility, research should focus on ways to enhance  $k_L a$  in the bioreactor, e.g., by the presence of organic products.

Promising processes for the conversion of syngas towards other products, such as fatty acids [7], acetone, iso-propanol and 2,3-butanediol [8] have been developed. For successful commercialisation of such processes, one could benefit a lot if the produced products are mass transfer-enhancing, like ethanol, or even better.

## 2.4. Conclusion

With a CFD model, which was validated using published data from a pilot-scale reactor, we investigated the hydrodynamics of a large-scale external-loop gas-lift reactor. With this model, the gas-liquid mass transfer was studied for an industrial CO-to-ethanol fermentation process. Several relations describing the mass transfer coefficient were evaluated and  $k_L a$  and mass transfer capacity were computed for varying process conditions.

At an operating temperature of 37°C, with increased gas hold-up compared to air-water and smaller bubbles ( $\leq 2$  mm instead of 5 to 7 mm), most available mass transfer relations predicted sufficient  $k_L a$  and *MTC* for an industrially viable syngas fermentation process, in line with data published by LanzaTech. We argue that this is possible since the produced ethanol inhibits bubble coalescence, causing smaller bubbles and increased gas hold-up. This indicates that typical mass transfer limitations encountered in air-water systems can be alleviated under industrial syngas fermentation conditions.

In spite of being computationally intensive, CFD can also be used for determining high-resolution process conditions that could not be accurately computed using simpler models. The developed hydrodynamic and mass transfer model can be used to advance research into reactor design for industrial syngas fermentation, for determination of the microbial response in such reactors using Euler-Lagrange modelling, and the development of scale-down simulators operated in a representative window.

## Abstract

In gas fermentations (using  $O_2$ ,  $CO$ ,  $H_2S$ ,  $CH_4$  or  $CO_2$ ), gas-to-liquid mass transfer is often regarded as one of the limiting processes. However, it is widely known that components in fermentation broths (e.g., salts, biomass, proteins, antifoam, and organic products such as alcohols and acids) have tremendous impact on the volumetric mass transfer coefficient  $k_La$ . We studied the influence of ethanol on mass transfer in three fermentation broths derived from syngas fermentation. In demineralized water, we observed that the addition of ethanol, the expected product, increased  $k_La$  two-fold in the  $0 - 5 \text{ gL}^{-1} \text{ h}^{-1}$  range, after which near-constant  $k_La$  values were obtained. In the fermentation broths,  $k_La$  was increased significantly (2 – 4 fold compared to water) by ethanol supplementation, and to be highly influenced by broth salinity. Our results indicate that  $k_La$  is a dynamic parameter in gas fermentation experiments and can be significantly increased due to broth components.

## Graphical abstract

### 3.1. Introduction

Many fermentations with gaseous substrates (e.g.,  $O_2$ ,  $CO$ ,  $H_2S$ ,  $CO_2$ ,  $CH_4$ ) are considered as promising conversion processes for a multitude of useful products (e.g., succinic acid, ethanol, butanol, hexanoic acid, lactic acid) [103, 174, 175], of which several are established in industrial practice [8, 28]. For many of these processes, poor gas-to-liquid mass transfer and low dissolved gas concentrations have been identified as a limiting factor [22, 25, 176, 177]. Based upon that, a lot of research, for example in syngas fermentation, is focused on increasing the volumetric mass transfer coefficient ( $k_L a$ ) by developing innovative reactor configurations [22, 23, 178]. Understanding of the  $k_L a$  values obtained is essential in the gas fermentation field.

For a long time, it has been known that medium components and products (such as salts, acids, alcohols, surfactants, biomass and antifoam) can significantly affect  $k_L a$  [155, 179–182]. For a broad range of alcohols in water, a fivefold increase in  $k_L a$  was observed in a narrow concentration range [155], which was explained by a decrease in Sauter mean bubble diameter ( $d_{32}$ ) (from 4 to 1 mm) and a twofold increase in the gas hold-up ( $\epsilon_G$ ) [37]. The presence of alcohol decreases the surface tension and stabilises low-diameter gas bubbles, leading to repulsions and thereby inhibiting coalescence [37, 157]. Similar effects on mass transfer were not only observed for alcohols, but also for organic acids, ketones and compounds like lactic acid [37, 182, 183]. Changes in the gas solubility at alcohol concentrations relevant for gas fermentations were, however, expected to be negligible [173].

Similar effects have been noticed for electrolytes. Lessard and Zieminski [180] observed significant coalescence inhibition (more than 90%) for different salt solutions with ionic strength above  $0.3 \text{ mol L}^{-1}$ , resulting in increases in  $k_L a$  values [155]. The presence of biomass, however, may decrease  $k_L a$  by absorption to the bubble surface (the so-called "blocking effect"), as well as by increasing the viscosity, which stimulates coalescence [179] and reduces the diffusion coefficient [143]. Dissolved proteins are known to improve mass transfer as they stabilise bubbles and prevent coalescence [181]. Furthermore, in air-water systems, the mass transfer coefficient ( $k_L$ ) is known to be, amongst others, a function of the bubble diameter: Small bubbles ( $d_b$  around 1 mm) have a rigid surface with a  $k_L$  around  $1 \times 10^{-4} \text{ ms}^{-1}$ , while larger bubbles ( $d_b > 2 \text{ mm}$ ) have a mobile surface and  $k_L$  between  $3$  and  $5 \times 10^{-4} \text{ ms}^{-1}$  [26].

Typically, biomass, salts, proteins, products, and substrates are jointly present in fermentation broth, and might change the medium physical properties (i.e., surface tension, viscosity, density) with respect to pure water. Some empirical relations (Table B.1) predict the influence of these properties on  $k_L a$  [25, 118–122]. As these relations have been developed using air-water mixtures without taking into account biomass and salts concentrations, their validity for fermentation broths remains unclear.

The aforementioned studies on mass transfer mostly focus on mixtures with water and one compound of interest, while the joint influence of different compounds has hardly been studied. Studies with fermentation broths have only been performed to characterise the effect of the biomass concentration on  $k_L a$  [179] and on  $d_{32}$  [184]. In wastewater technology, however, it is common to measure aeration performance in process water (with contaminants and biomass sludge), which is often characterised with the alpha-factor, which relates the  $k_L a$  in process water with clean water [185]. Analyses on the joint influence of broth components in gas fermentations on mass transfer are lacking in the scientific literature, making it challenging to estimate. Knowledge on the most influential parameters and their respective ranges would be essential for accurate prediction in real fermentation broths, both during experiments and modelling. With the growing interest in fermentation and bioprocess design, understanding on the most influential parameters and their respective ranges would be essential for accurate  $k_L a$  prediction.

In this study, we aim to determine mass transfer characteristics ( $k_L a$ ,  $d_{32}$ ,  $\varepsilon_G$ ,  $k_L$ ) in different fermentation broths to show that there are complex interactions between the compounds present and that this has significant consequences in gas fermentation processes. Syngas fermentation is used as an example of a gas fermentation process, as it is a frequently studied process wherein mass transfer is often mentioned as a factor for poor performance [22, 23]. For safety and analytical reasons, oxygen mass transfer is studied, but the same trends are expected for other gases that also have a very low solubility in water, such as CO, H<sub>2</sub>S, and CH<sub>4</sub>. The very low concentration of dissolved O<sub>2</sub> is expected not to change  $k_L a$ ,  $d_{32}$ ,  $\varepsilon_G$ , or  $k_L$ . The investigated product is ethanol, since it is a major product in the commercialised syngas fermentation process [10]. First, we will determine the range wherein ethanol addition affects  $k_L a$ . After that, we will study the influence of ethanol on the mass transfer characteristics in five mixtures (water, fermentation medium, and three syngas fermentation broths). The experimentally obtained  $k_L a$  values will be compared with  $k_L a$  values from published empirical relations, after determining the physical properties of the mixtures.

## 3.2. Materials and methods

### Influence of ethanol concentration on $k_L a$

$k_L a$  was determined in water-ethanol solutions using the dynamic absorption method [25] in a 1.5 L temperature-controlled stirred tank reactor (STR) with 1 L working volume (Applikon Biotechnology, the Netherlands). After desaturation with pure nitrogen, dissolved oxygen (DO) was measured every second with an AppliSens Dissolved Oxygen probe (Applikon Biotechnology, the Netherlands) while supplying 1 vvm of air at 800 rpm stirring rate. Experiments were performed at 20 °C and 37 °C and at least in threefold for all demineralized water-ethanol mixtures (with 0, 2.5, 5, 10, 15, 25 and 50 gL<sup>-1</sup>).

### Mass transfer characteristics of different mixtures

Several mixtures were tested in a bubble column reactor (BCR): demineralized water, mineral fermentation medium ("medium"), and three fermentation broths derived from syngas fermentation experiments (e.g., "broth-1"). A BCR was used since it enables more detailed analyses on  $d_b$  and  $\varepsilon_G$  than a STR does. The influence of ethanol on the mass transfer characteristics was determined by supplementing with the industrially obtained ethanol concentration (50 gL<sup>-1</sup>) [111], after experiments without supplemented ethanol. The Supplementary material provides the composition of the mineral fermentation medium as well as the media and methods for cultivation of the fermentation broths (Table B.2).

Mass transfer characteristics of the different mixtures were determined in a lab-scale glass bubble column (7 cm internal diameter, 70 cm liquid height) with a multi-orifice sparger (0.6 mm orifice diameter). Experiments were performed with air at a low superficial gas flow velocity of 1.8 mm s<sup>-1</sup> to ensure that flow was homogeneous and that the individual bubbles could be pictured for bubble size determination. The liquid temperature was kept at 37 °C. Gas hold-up was determined by measuring the ratio between aerated and unaerated volumes [156] using a ruler at the column wall.  $k_L a$  was determined using the same method as described above, with the oxygen probe located 42 cm above the sparger, at least in triplicate for each mixture.

The bubble size was analysed using two methods, one for the small bubbles in mixtures with supplemented ethanol and another for larger bubbles in the mixtures without ethanol. During aeration, pictures of the small bubbles were made with a photo-optical endoscopic probe (SOPAT-VF GX 2750) (SOPAT, Germany) with the focal plane at 0.5 mm, located 47 cm above the sparger. From 600 images, between 100 and 1400 bubbles (depending on the mixture) were captured with the Hough circle detection method in the Python OpenCV package, and their diameters were calculated using a camera-specific pixel-to-mm conversion factor. As these bubbles were spherical, the Sauter mean bubble diameter  $d_{32}$  was calculated using Equation 3.1, in which  $V_{b,i}$  is the volume of bubble  $i$ ,  $A_{b,i}$  its surface area and  $d_{b,i}$  its diameter.

$$d_{32} = 6 \frac{\sum_i V_{b,i}}{\sum_i A_{b,i}} = 6 \frac{\frac{4}{3}\pi \sum_i \left(\frac{1}{2}d_{b,i}\right)^3}{4\pi \sum_i \left(\frac{1}{2}d_{b,i}\right)^2} \quad (3.1)$$

To obtain the (equivalent) diameter of the larger bubbles, pictures were made with a CANON EOS 200D camera. A metal ruler was placed inside the column to decrease the influence of light refraction and to obtain a pixel-to-mm ratio. With image analysis software (ImageJ)  $d_b$  was measured for spherical bubbles, and for spheroidal bubbles the radii of the semi-major  $r_a$  and semi-minor axes  $r_c$  were measured to determine their eccentricity  $e$  and equivalent diameter  $d_{eq}$  of bubble  $i$  (Equation 3.2). Subsequently,  $d_{32}$  was calculated with the obtained (equivalent) diameters of the spherical and spheroidal bubbles using Equation 3.1. The two bubble size determination methods were cross-validated using broth-4, see Figure B.1 and Table B.3.

$$d_{eq,i} = 6 \frac{V_{b,i}}{A_{b,i}} = 6 \frac{\frac{4}{3}\pi r_a^2 r_c}{2\pi r_a^2 + \pi \frac{r_c^2}{e} \ln\left(\frac{1+e}{1-e}\right)} \text{ with } e = \sqrt{1 - \frac{r_c^2}{r_a^2}} \quad (3.2)$$

After determining  $d_{32}$ ,  $k_L a$  and  $\varepsilon_G$ , Equation 3.3 was used to calculate  $k_L$ .

$$k_L = \frac{k_L a}{a} \text{ with } a = \frac{6\varepsilon_G}{d_{32}} \quad (3.3)$$

The standard deviation  $\sigma$  of  $k_L$  was evaluated using classical error propagation (Equation 3.4). The unpaired  $t$ -test with Welch's correction was used to determine statistical significance for all mass transfer characteristics.

$$\sigma_{k_L} = k_L \sqrt{\frac{\sigma_{k_L a}^2}{k_L a} + \frac{\sigma_a^2}{a}} \text{ with } \sigma_a = a \sqrt{\frac{\sigma_{\varepsilon_G}^2}{\varepsilon_G} + \frac{\sigma_{d_{32}}^2}{d_{32}}} \quad (3.4)$$

### Determination of mixture properties

After aeration in the BCR, the mixtures' physical properties were determined at 37 °C. Density was measured with a benchtop density meter (DMA 5000, Anton Paar, Austria). The dynamic viscosity was determined with a Haake Viscotester 500 (Thermo Fisher Scientific, US) with NV sensor system. Dynamic surface tension was measured using a BPT Mobile tensiometer (KRÜSS Scientific, Germany), at least in duplicate.

The biomass concentration for fermentation broth-2, broth-3 and broth-4 was measured by determination of volatile suspended solids (VSS) concentration in the broth, from 150 mL broth samples [186]. For broth-1, the biomass concentration was obtained by measuring its optical density at 660 nm (OD<sub>660</sub>). This was converted to VSS concentration using calibration curves previously obtained during cultivation. Acetate and ethanol concentrations in filtered broth samples (0.22 µm pore size, Millipore, Millex-GV, Ireland) were determined using ultra high performance liquid chromatography (UPLC) with an Aminex HPX-87H column (BioRad, United States) at 50 °C coupled to a refractive index

(RI) detector RefractoMax 520 (Thermo Fisher Scientific, US), using 1.5 mmolL<sup>-1</sup> aqueous phosphoric acid as eluent. Lastly, protein concentrations were determined with the Pierce<sup>TM</sup> BCA Protein Assay Kit (Thermo Fisher Scientific, US) according to the manufacturer recommendations. From the cultivation media composition (Table B.2), ionic strength  $I$  was calculated (Equation 3.5), from each ion concentration  $c$  and charge  $z$ .

$$I = \frac{1}{2} \sum_i c_i z_i^2 \quad (3.5)$$

### 3.3. Results and discussion

In this section, we will first present the influence of the concentration of ethanol in water on the  $k_L a$ , which was determined in a stirred tank reactor (section 3.3.1). After that, detailed results for the different mixtures in a bubble column reactor will be presented (section 3.3.2), which will be followed by a discussion on  $k_L$  for fermentation broths (section 3.3.3). Lastly, a comparison with empirical correlations (sections 3.3.4) will be performed with the determined physical properties.

#### 3.3.1. Influence of ethanol on $k_L a$

The influence of the ethanol concentration in water on  $k_L a$  has been determined in a stirred tank (Figure 3.1). Sharp increases in  $k_L a$  values were observed in the lower concentration range, until a plateau was reached (between 5 – 10 gL<sup>-1</sup>, independent from the temperature). For both temperatures, the maximum  $k_L a$  value was about twice as large as it would be without ethanol. Visually, we observed a significant reduction in bubble size upon the addition of ethanol, explaining the increased  $k_L a$  value (Figure B.4).

The  $k_L a$  value increases roughly 40% between 20 and 37°C, which corresponds with predictions for this temperature-increase [26, 117]. The results obtained for these two temperatures indicate that the temperature-increase and the ethanol addition most likely show an independent influence on  $k_L a$ . This temperature increase predominantly causes an increase in  $k_L$  (by increasing the diffusion coefficient, and reducing the kinematic viscosity [142, 143]).

In STRs with added ethanol, similar increases in  $k_L a$  have been observed before [187], but not with such a clear plateau formation. The plateau formation in  $k_L a$  has been observed for other organic compounds in STRs [155], and has been explained by the constant bubble diameter beyond a certain concentration range [37]. Similar results on plateau formation have been seen in a plunging jet contactor with propanol [188] and in an external-loop airlift reactor with methanol, ethanol and propanol [189].

The ethanol concentration range in which the steep change in  $k_L a$  values was observed (0 – 5 gL<sup>-1</sup>) corresponds to the range of ethanol titres achieved in lab-scale syngas fermentation experiments, for example [17, 22, 90]. The rapid ethanol concentration change within this range indicates that  $k_L a$  is not a constant but a dynamic parameter during gas fermentation processes. For example, during batch operation, different values of  $k_L a$  may apply. Moreover, we recommend to obtain  $k_L a$  values using representative fermentation conditions rather than using water, to compare reactor configurations [178, 190] or to determine dissolved gas concentrations [191].

Consequently, we expect that  $k_L a$  differs between fermentation broths derived from syngas fermentation experiments and synthetic aqueous solutions containing some broth solutes. As more detailed analyses on  $d_b$  and  $\varepsilon_G$  can be performed in BCRs, we will use BCRs in the upcoming sections. Due to the plateau formation by ethanol addition, we will perform experiments with the expected industrial  $c_{\text{EtOH}}$  of 50 gL<sup>-1</sup> [111].

### 3.3.2. $k_La$ determination in different mixtures with ethanol

The determined physical properties of the mixtures are shown in Table 3.1. As the fermentation broths contain only little amounts of ethanol, we supplemented the mixtures with ethanol to reach the industrially relevant concentration (50 gL<sup>-1</sup>). A clear decrease in surface tension occurs upon supplementation of ethanol. Broth-4 was not included in the table as there was possible interference with the reducing agent during the  $k_La$ -

determination (see section 3.3.5), such that the  $k_L a$  and  $k_L$  values could not be predicted reliably.

For all other mixtures, a significant increase in  $k_L a$  is observed (Figure 3.2a) upon the addition of ethanol ( $p = 0.038$ ). In water, a sixfold higher  $k_L a$  is encountered after adding ethanol. Such increases have been obtained before with ethanol [155, 158]. This is explained by the decrease in  $d_{32}$  (from 2.7 mm to 0.7 mm) and the doubling of the gas hold-up due to the addition of ethanol.

The mineral medium and broth-1 show an increased  $k_L a$  compared to the demineralized water. This might be due to their high ionic strength ( $0.3 \text{ mol L}^{-1}$ , Table 3.1) since little coalescence was expected when ionic strength is above  $0.2 \text{ mol L}^{-1}$  [180]. This suggests that  $k_L a$  might easily be increased in fermentation broths by increasing ionic strength by slightly changing the mineral medium composition.

Although ethanol decreases the bubble size and makes the bubbles more spherical and rigid (Figure B.3), the beneficial effect of ethanol on  $k_L a$  is less pronounced in the mineral medium than in pure water. This lower increase in  $k_L a$  can be attributed to a decrease in  $k_L$ , which might be due to unresolved complex interactions between salts and ethanol in the boundary layers.

For all fermentation broths,  $k_L a$  is observed to be lower than in the mineral medium. As  $d_{32}$  and  $\varepsilon_G$  remain similar in broth-1 and broth-2, the decrease in  $k_L a$  is attributed to a decrease in  $k_L$  (see section 3.3.3), resulting in broth-2 and broth-3 having a similar  $k_L a$  as water (without ethanol). Hence, the presence of biomass in these broths seems to diminish the beneficial effects of salts on  $k_L a$ . Supplemented ethanol causes a decrease in  $d_{32}$ , but the net increase in  $k_L a$  is less pronounced than for the mineral medium. Still, the  $k_L a$  values in the ethanol-rich broths are two to four times larger than the value in water without ethanol, indicating that the mass transfer properties of these broths can neither be represented by those of pure water, nor by those of water with added ethanol only.

In all cases with ethanol, a significant decrease in bubble diameter is observed ( $p = 0.023$ ), as well as a narrower bubble size distribution by analysing the standard deviations (Figure 3.2b) and the bubble size distribution plots (Figure B.4). This confirms that ethanol stabilises the homogeneous flow regime [156, 160], while the coalescence inhibition causes a hold-up increase (Figure 3.2c) [157].

In the mineral medium and fermentation broths,  $d_{32}$  does not change much, except for some decrease with broth-3. This implies that the biomass, acetate and proteins have little effect on the bubble size at the observed concentrations. Broth-3 also shows a remarkably low  $d_{32}$  without ethanol, compared to the other mixtures. This effect cannot be explained, because more data are required to achieve correlation to the physical properties or the concentration of components.

The addition of ethanol significantly ( $p = 0.0003$ ) increases the gas hold-up for all media (Figure 3.2c). Increases in gas hold-up have been explained by coalescence inhibition:

Figure 3.2: Mass transfer characteristics obtained in a bubble column ( $u_{G,s} = 1.8 \text{ mm s}^{-1}$ ) for different mixtures (see Table 1) without (white bars) and with supplemented ethanol (patterned bars). a) Volumetric mass transfer coefficient  $k_L a$ , b) Sauter mean bubble diameter  $d_{32}$ , c) gas hold-up  $\varepsilon_G$ , and d) mass transfer coefficient  $k_L$ . Error bars: standard deviations between at least three measurements.

smaller bubbles rise slower, thereby increasing the gas residence time in the reactor and thus the hold-up [157]. The same applies for the mineral medium and broths: salts and surface-active compounds decrease  $d_{32}$  by inhibiting coalescence and thus increase the hold-up. For more details about the underlying mechanisms, one is referred to Keitel and Onken [37] and Jamialahmadi and Müller-Steinhagen [157].

The obtained data hint at a decrease in  $k_L$  due to supplemented ethanol (Figure 3.2d), but this was not statistically significant ( $p = 0.10$ ). A decrease would be explained by an ethanol layer causing extra mass transfer resistance around the gas bubble, or by increasing surface rigidity due to the small and spherical bubbles.

3

### 3.3.3. $k_L$ as function of biomass concentration

From the different mixtures, it was observed that the fermentation broths have a lower  $k_L$  than water. This weakly correlates (Pearson's  $r = -0.57$ ) with the biomass concentration in the broth (Figure 3.3). It has been argued [25] that biomass increases broth viscosity and thus decreases  $k_L$ . However, the viscosities of the measured samples are in such a narrow range that a viscosity-based  $k_L$ -model cannot adequately describe these changes [131] (Figure B.5). Any such reduction might be explained by a bubble surface blocking effect of the biomass, creating additional mass transfer resistance, even though direct oxygen consumption was not expected for syngas fermenting bacteria [25]. We expect that there are complex interactions between the (type of) microbe, salts and nutrients in the medium, and the products that influence the value of  $k_L$ . Unfortunately, at this moment, we are not able to provide general guidelines for prediction of  $k_L$  in fermentation broths without further experiments.

### 3.3.4. Comparison with empirical correlations

Empirical relations (Table B.1) are often used for the prediction of  $k_L a$  in bubble column fermentations [25]. After determining surface tension, density and viscosity for all the different media (with and without ethanol) (Table 3.1), the  $k_L a$  values were calculated using these equations (Figure 3.4). However, a large discrepancy is visible between the experimental and predicted values. These relations systematically underestimate  $k_L a$  since they do not consider the influence of biomass, the salts and ethanol on the bubble properties. For example, the decrease in surface tension by ethanol has a smaller influence on  $k_L a$  in the empirical relations than observed in our experiments. As we saw that variables such as ionic strength, ethanol and biomass concentration are important regarding mass transfer in fermentation broths, these variables should also be part of such relationships.

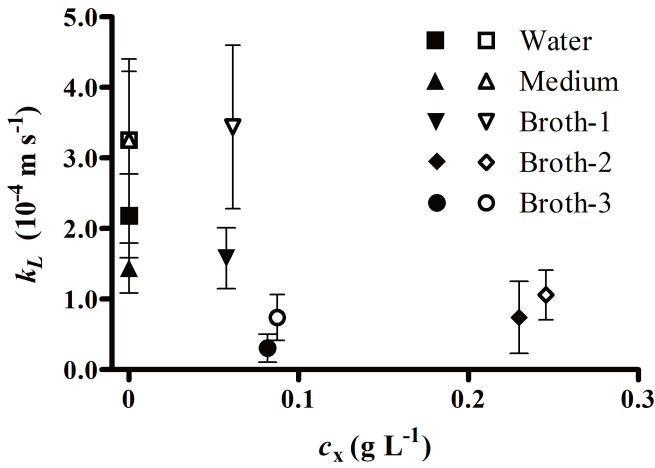

Figure 3.3: Mass transfer coefficient  $k_L$  for different values of the biomass concentration in the studied mixtures. Open symbols: mixtures without ethanol, filled: mixtures with 50  $\text{g L}^{-1}$  ethanol. Error bars: standard deviations.

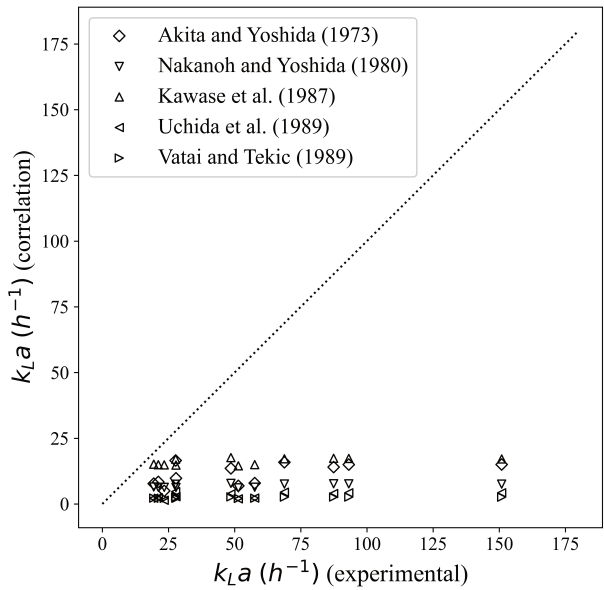

Figure 3.4: Parity plot of experimental  $k_L a$  data in the different mixtures vs. the values calculated using empirical relations: Akita and Yoshida [118], Nakanoh and Yoshida [119], Kawase et al. [120], Uchida et al. [121], Vatai and Tekić [122].

### 3.3.5. Implications and future studies

This study shows several mass transfer characteristics obtained in different liquid mixtures relevant for gas fermentations. The obtained results show that the influence of medium components is significant and should be considered in future experimental and modelling work in gas fermentations. Our results are highly applicable to (industrial) practitioners of gas fermentation experiments as these can be beneficial for accurate determination of  $k_L a$  and provides means to increase the  $k_L a$  value by tuning medium composition.

Although it is widely known that antifoam promotes coalescence [25, 181] and decreases mass transfer by creating a monolayer around the bubbles [192], and that dissolved solids (e.g., silica) can both improve and worsen mass transfer (depending on the concentration) [170], we did not consider their presence. Furthermore, only one mass transfer enhancing agent was studied (ethanol) for only one type of gas fermentation broths (derived from syngas) with a limited range of biomass concentrations (0–0.5 g L<sup>-1</sup>).

To reduce the redox potential, which is required for anaerobic (syngas) fermentation, a reducing agent was added to the fermentation broths (Table B.2). Reaction of oxygen and the reducing agent (sodium sulphide) might have disturbed the dynamic absorption method for  $k_L a$  determination (for broth-4), such that this broth had to be left out from the aforementioned evaluation. In such a case the method might be adapted to, for example, the method proposed by Bandyopadhyay et al. [193]. Future studies should also note that the dynamic absorption method for  $k_L a$  determination has low validity at high power inputs ( $P/V > 1000 \text{ W m}^{-3}$  [194]. Considering that in air-water systems  $P/V$  is a critical variable determining the  $k_L a$  value [25, 195], further research should be done to determine the influence of  $P/V$  in cases with ethanol. Therefore the influence of variable superficial gas velocities (in BCRs and STRs) and stirrer speeds could be studied (STRs).

Industrial syngas fermentation requires higher biomass concentrations (around 10 g L<sup>-1</sup>) [32] than the concentrations achieved in our experiments. Such high biomass concentrations are expected to influence the broth viscosity and thus the  $k_L$ . Furthermore, the used bubble column (7 cm diameter) is not representative for an industrial fermentation. To represent a large-scale bubble column, the column diameter should be more than 15 cm to exclude wall effects for mild viscous liquids [196]. For an industrial-scale syngas fermentation, a significantly higher gas flow velocity can be expected. We noted by using such gas velocities in this column, determination of  $d_{32}$  in media without ethanol would be challenging due to the regime change to slug flow. To prevent slugs, we decided to compare  $d_{32}$  and  $k_L a$  at low gas flow velocities. In literature, at higher gas flow rates and in wider and higher columns, the beneficial effect of ethanol on gas hold-up [156, 160] and  $k_L a$  has been observed [189]. Therefore, we think that the phenomena reported in this paper will also be present in large-scale reactors.

Our research indicates that other aspects of broth composition (next to ethanol content) influence mass transfer that is currently not well understood. Further research is needed to quantitatively predict the relevant parameters (e.g.,  $k_L$ ,  $d_{32}$ ) in order to develop more realistic mass transfer models for fermentations. Although the exact mechanism might remain unknown, systematic experiments and technologies like machine learning might be used to develop algorithms for reliable prediction of mass transfer properties in fermentation broths of various compositions. Unravelling the mechanisms behind our observations (e.g., why  $k_L a$  is lower in the mixture with mineral medium and ethanol compared to the water-ethanol mixture) will require additional and more fundamental studies, which could guide the development of mechanistic models.

Although our results were only obtained with supplemented ethanol, we stress that similar phenomena have been obtained with other compounds (longer alcohols, acids, ketones) [37, 155, 182]. This indicates that similar deviations in mass transfer characteristics can be expected in a wide range of gas fermentations [174], e.g., syngas fermentation (to alcohols/acids), microbial electrosynthesis (to acids) [176] as well as aerobic sugar-based fermentations (e.g., 1,4-butanediol production [27]). As there are methods available to measure mass transfer characteristics ( $k_L a$ ,  $d_{32}$ ,  $\varepsilon_G$ ,  $k_L$ ,  $a$ ) easily, we highly recommend to perform these experiments with realistic broths to prevent underestimation of mass transfer rates.

### 3.4. Conclusion

By supplementing ethanol to water,  $k_L a$  sharply and significantly increases, primarily by decreasing  $d_{32}$ . This effect is also present, but weaker, in the studied syngas fermentation broths. Broth salinity (ionic strength) and biomass concentration seem to affect  $k_L a$  in fermentation broth as well. Future mass transfer studies should consider the influence of broth components because literature models fail to predict their effects.

# Chapter 4

## Downscaling gas fermentation by taking the microbial perspective

*Waar de werkelijkheid ontbreekt, daar is de schijn het beste*

Desiderius Erasmus

---

This chapter has been published as:

Puiman, L., Almeida Benalcázar, E., Picioreanu, C., Noorman, H. J., & Haringa, C. (2023). Downscaling industrial-scale syngas fermentation to simulate frequent and irregular dissolved gas concentration shocks. *Bioengineering*, 10(5), 518.

## Abstract

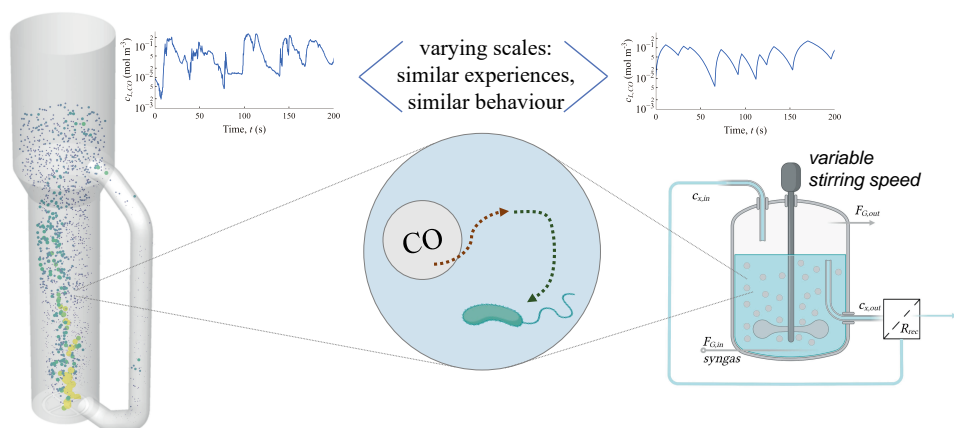

In large-scale syngas fermentation, strong gradients in dissolved gas ( $\text{CO}$ ,  $\text{H}_2$ ) concentrations are very likely to occur due to locally varying mass transfer and convection rates. Using Euler-Lagrangian CFD simulations, we analysed these gradients in an industrial-scale external-loop gaslift reactor (EL-GLR) for a wide range of biomass concentrations, considering  $\text{CO}$  inhibition for both  $\text{CO}$  and  $\text{H}_2$  uptake. Lifeline analyses showed that microorganisms are likely to experience frequent (5 to 30 s) oscillations in dissolved gas concentrations with one order of magnitude. From the lifeline analyses we developed a conceptual scale-down simulator (stirred-tank reactor with varying stirrer speed) to replicate industrial-scale environmental fluctuations at bench-scale. The configuration of the scale-down simulator can be adjusted to match a broad range of environmental fluctuations.

Our results suggest a preference for industrial operation at high biomass concentrations as this would strongly reduce inhibitory effects, provide operational flexibility, and enhance the product yield. The peaks in dissolved gas concentration were hypothesised to increase the ethanol yield due to the fast  $\text{CO}$ -uptake mechanisms in *C. autoethanogenum*. The proposed scale-down simulator can be used to validate such results and to obtain data to parameterise lumped kinetic metabolic models that describe such short-term responses.

## Graphical abstract

Industrial-scale ( $500 \text{ m}^3$ ) syngas fermentation

Lab-scale (2 L) syngas fermentation

## 4.1. Introduction

Syngas fermentation is nowadays an established process for the conversion of waste gases into chemicals [8, 10]. The company LanzaTech successfully commercialises the fermentation of synthesis gas (containing CO, H<sub>2</sub> and CO<sub>2</sub>) into ethanol, and is currently exploring other products such as acetone and isopropanol [9]. Although mass transfer limitations have often been accounted as a limiting factor for scale-up of syngas fermentation, such limitations could highly be relieved by making products which are bubble coalescence-suppressing, such as ethanol [197].

High product specificity towards ethanol (> 90%) is required for successful commercialisation [8]. In a process called solventogenesis, *Clostridium autoethanogenum*, the workhorse of industrial-scale syngas fermentation, produces ethanol from syngas (e.g., using Reaction 4.1 and 4.2), while during acetogenesis syngas is converted into acetate [14, 198]. Solventogenesis can be triggered by low extracellular pH [11], by high extracellular concentrations of acetate [199], or by H<sub>2</sub> supplementation [46].

Since industrial-scale reactors are of considerable size (e.g., 5 m diameter by 25 m height, or ~500 m<sup>3</sup>, is not exceptional), the occurrence of spatial gradients is more of a rule than an exception. Usually substrate gradients occur when the characteristic time of reaction  $\tau_{\text{rxn}}$  is significantly lower than the characteristic time of transport, which is related to mixing for substrates in the liquid phase via the circulation time ( $t_c$ ), and to mass transfer for gaseous-phase substrates ( $\tau_{\text{MT}}$ ) [48, 49]. For large-scale syngas fermentation,  $\tau_{\text{rxn}}$  is expected to be much lower (~0.3 s; [40]) than  $\tau_{\text{MT}}$  (around 10 – 20 s; [197]) and  $t_c$  (~40 s; Figure C.1). Furthermore, both hydrostatic pressure differences (3.5 bar at the bottom vs. 1 bar near the headspace) and gas mole fraction differences (e.g.,  $y_{\text{CO}}$  decreases from 50% to 5% from bottom to top due to consumption) cause a gradient of around factor 35 in saturation concentration, while the volumetric mass transfer coefficient  $k_L a$  might be locally varying due to turbulent fluctuations, differences in bubble size and gas hold-up [197]. We hypothesise that all of this leads to sizeable dissolved CO and H<sub>2</sub> concentration gradients which might have implications on the syngas fermentation performance.

The impact of such concentration differences on *C. autoethanogenum* can be studied with Euler-Lagrangian CFD modelling. This way environmental changes, for example in substrate concentration, temperature, and shear stress, can be recorded from the perspective of the microbe (the so-called *lifeline*) [62, 64, 66]. The cells are simulated as Lagrangian flow-followers (particles) and, when they do not interact with the flow or concentration field (one-way coupling), are used for analysing the environmental fluctuations occurring in the bioreactor [56, 57, 200]. Such analyses could be used for the development of scale-down simulators [165, 201] or to study cell population heterogeneity [202]. Two-way coupling has to be realised when studying the influence of biomass

on the flow or concentration fields [58, 99]. This method requires the use of a structured metabolic-kinetic model that could be coupled with the CFD model in a computationally viable fashion [66]. Although very detailed genome-scale metabolic models and kinetic ensemble models are currently available for *C. autoethanogenum* and other acetogens [46, 62, 203], two-way coupling of these models is currently too computationally intensive for practical application. Development of less-detailed, yet structured kinetic models by metabolite lumping [67, 68, 94] is key to study the influence of *C. autoethanogenum* on the flow and concentration fields more accurately.

Siebler et al. [56] studied how *C. ljungdahlii* would respond to CO gradients in a severely mass transfer limited bubble column reactor. They hypothesised based upon their Euler-Lagrangian results and in analogy with *Escherichia coli* that in their case transcriptional changes were very likely (>84%) to occur because long-lasting CO limitations would lead to a maintenance-dominated metabolism. Redox-controlled oscillations in biomass-specific uptake and production rates were observed in *C. autoethanognum* [204], within the timescale of hours, while substrate fluctuations in the order of seconds ( $\sim t_c$ ) or minutes are expected in the large-scale. With scale-down simulators (e.g., based on a single-vessel, multiple vessels such as stirred tank reactors coupled with plug flow reactors, or microfluidics) the physiological cell response on such short-term fluctuations could be studied so that the large-scale environment as experienced by the cell is reproduced at bench-scale [48, 64–66, 205]. The obtained metabolite fluctuations can be used for parametrisation of the lumped metabolic models [67].

Several scale-down simulators have been developed and used in the past decades, but the requirements of a scale-down simulator for syngas fermentation have not been identified yet. Since there are many unknowns in the scientific literature regarding kinetics and short-term cell responses, the execution of scale-down experiments that are representative of the large-scale behaviour is crucial for advancing the syngas fermentation field. In this study, we propose a scale-down simulator to study industrial-scale syngas fermentation at lab-scale. To exemplify the distinctive applicability of the proposed scale-down simulator, a wide range of industrial biomass concentrations were studied, since this is a major determinant for the dissolved gas concentration. The impact of gas (CO<sub>2</sub>) production on the dissolved gas concentration gradients and thus possible fluctuations for the microbe was studied. We used our previous CFD model of an industrial-scale external-loop gaslift reactor (EL-GLR) and our lab observations to develop and analyse lifelines representative for large-scale syngas fermentation [197, 206].

## 4.2. Methods

### Eulerian concentration field

#### Geometry and flow field

As a starting point for the simulations, the 3D reactor geometry and computed flow field of the EL-GLR were used, for which the modelling approach was validated on pilot-scale data as described in [197]. The only change was the syngas composition from a 50% CO, 50% N<sub>2</sub> mixture to a 50% CO, 20% H<sub>2</sub>, 30% CO<sub>2</sub> (v/v) mixture [204]. Since the average molar mass of these compositions is similar and the ideal gas law applies, the mass-flow inlet boundary condition of 2.11 kg s<sup>-1</sup> was kept the same, as well as the headspace pressure of 101 kPa.

Next to the equations for gas and liquid flow, volume fraction, and turbulence, the species equations were solved transiently for both phases for obtaining the concentration fields, by implementing user-defined functions (UDFs) for both mass transfer and biological reaction (Figure 4.1), in ANSYS Fluent 2021R1.

#### Mass transfer model

The mass transfer coefficient  $k_L$  was computed by taking the maximum value derived from either the Higbie [127] (Equation 4.3) or the Lamont-Scott relation [131], the result of the latter was corrected for the underestimation of the energy dissipation rate  $\epsilon$  by the

Getinge Applikon 3 L glass bioreactor

Figure 4.1: Conceptual representation of the modelling procedure for both a) the industrial-scale reactor and b) the scale-down simulator. The 3D geometry, based on publicly available pictures of the Shougang-LanzaTech plant, the hydrodynamic model CFD of the EL-GLR and its validation on pilot-scale data are extensively described in our previous work [197]. The scale-down simulator is based upon a 3 L bioreactor (2 L liquid volume), with varying duration of high and low stirrer speed after the start-up phase. See Table C.1 for details on the geometry of this reactor [207]. Created with BioRender . com.

$k$ - $\epsilon$  model [165] using the pneumatic power input derived from standard correlations [166] and the liquid volume integral of  $\epsilon$  (Equation 4.4). The maximum  $k_L$  of species  $i$  was used to account for both surface layer renewal mechanisms, since high  $k_L$  might be obtained in zones with high energy dissipation [164], but transfer in low-turbulent conditions is better approximated by the Higbie relation [26].

$$k_{L,i} = 2\sqrt{\frac{D_{L,i} v_{\text{slip}}}{\pi d_b}} \quad (4.3)$$

$$k_{L,i} = 0.45 D_{L,i}^{\frac{1}{2}} (\epsilon_{\text{cor}} / v_L)^{\frac{1}{4}} \text{ with } \epsilon_{\text{cor}} = f_{\text{cor}} \epsilon_{\text{local}} \text{ and } f_{\text{cor}} = \frac{P_{\text{in}}}{\int_{V_L} \epsilon_{\text{local}} dV_L} \quad (4.4)$$

4

In order to obtain a realistic mass transfer rate for industrial-scale syngas fermentation, spherical bubbles with constant diameter (3 mm) were assumed based upon our previous work [197] (Equation 4.5). Since coalescence could be suppressed by the presence of surface-active compounds (e.g., ethanol, salts) in syngas-to-ethanol fermentations, small bubbles can be obtained, leading to high mass transfer rates [157, 181, 200, 206].

While our multiphase model accounted for mass loss through interphase mass transfer and gas expansion using the ideal gas law in Fluent's volume fraction equation [79], we acknowledge that bubble coalescence, break-up, shrinkage by consumption, and pressure-based bubble expansion were not considered by assuming a constant bubble size. Although these factors could have potentially improved the accuracy of the gas phase description, we chose to prioritise obtaining realistic gas mass transfer rates and focusing on the biological aspects of our study. Therefore, we opted for a simplified set of equations, similar to Siebler et al. [56], that were within the scope of our work.

The saturation concentration was calculated considering the local gas phase mole fraction. The pH equilibrium of  $\text{CO}_2$  with carbonate species could increase the gas-to-liquid mass transfer rate in neutral (pH 6 - 8) and basic conditions (pH > 8), however this effect can be neglected as the syngas fermentation process is operated at pH 5. To ensure complete saturation of CO,  $\text{H}_2$ , and  $\text{CO}_2$ , and achieve steady-state conditions (i.e., statistically stationary) in the average flow and concentration fields, the mass transfer model was run for 1000 s. Although short-time fluctuations occurred, there were no long-term dynamics, as evidenced by the constant rolling average of the global gas hold-up and dissolved gas concentrations.

$$MTR_i = k_{L,i} a \Delta c_{L,i} = k_{L,i} 6 \frac{\epsilon_G}{d_b} (H_i p y_i - c_{L,i}) \quad (4.5)$$

### Biological reaction modelling

The biomass-specific CO and  $\text{H}_2$  uptake rates ( $q_i$ ) were modelled using a recently derived kinetic model [40]. Both CO- and  $\text{H}_2$ -uptake models account for CO inhibition (Equation 4.6 and 4.7), and are based on models derived by Mohammadi et al. [34] and de Medeiros et al. [208], respectively.

Table 4.1: Parameters used for the simulation of the Eulerian concentration field.

Name	Symbol	CO	H <sub>2</sub>	CO <sub>2</sub>	Unit	Source
Inlet gas fraction	$y_{i,\text{in}}$	0.5	0.2	0.3	$\text{mol}_i \text{ mol}_G^{-1}$	[204]
Henry coeff.	$H_i$	$2.30 \times 10^{-7}$	$1.47 \times 10^{-8}$	$1.06 \times 10^{-5}$	$\text{kg m}^{-3} \text{ Pa}^{-1}$	[144]
Diffusion coeff.	$D_{L,i}$	$2.71 \times 10^{-9}$	$6.01 \times 10^{-9}$	$2.56 \times 10^{-9}$	$\text{m}^2 \text{ s}^{-1}$	[143]
Maximum uptake rate	$q_i^{\text{max}}$	1.459	2.565	-	$\text{mol mol}_x^{-1} \text{ h}^{-1}$	[40]
Half-saturation coeff.	$K_{S,i}$	0.042	0.025	-	$\text{mol m}^{-3}$	[40]
Inhibition coeff.	$K_I$	0.246	-	-	$\text{mol m}^{-3}$	[40]
	$K_{I,\text{CO}}$	-	0.025	-	$\text{mol m}^{-3}$	[40]

$$q_{\text{CO}} = q_{\text{CO}}^{\text{max}} \left( \frac{c_{L,\text{CO}}}{K_{S,\text{CO}} + c_{L,\text{CO}} + \frac{c_{L,\text{CO}}^2}{K_I}} \right) \quad (4.6)$$

$$q_{\text{H}_2} = q_{\text{H}_2}^{\text{max}} \left( \frac{c_{L,\text{H}_2}}{K_{S,\text{H}_2} + c_{L,\text{H}_2}} \right) \left( \frac{1}{1 + \frac{c_{L,\text{CO}}}{K_{I,\text{CO}}}} \right) \quad (4.7)$$

The overall reaction rate  $r_i$  is the product of  $q_i$  and the biomass concentration  $c_x$ , the latter was assumed to be spatio-temporally constant as a continuous process is considered in steady state. The reaction rates were enabled once CO and H<sub>2</sub> concentrations reached a steady saturation value. Once statistically stationary flow and concentration fields were obtained (after 600 s the rolling averages of the global dissolved gas concentrations and hold-up remained constant), time-averaged fields were collected over an averaging period of 200 s. Parameters used for computing the Eulerian concentration fields are provided in Table 4.1.

The influence of microbial CO<sub>2</sub> production was examined by modelling two extreme cases at 25 gL<sup>-1</sup> biomass: *i*) only CO<sub>2</sub> consumption by H<sub>2</sub> catabolism,  $q_{\text{CO}_2} = -\frac{1}{3} q_{\text{H}_2}$ , and *ii*) also including production by CO catabolism:  $q_{\text{CO}_2} = \frac{4}{6} q_{\text{CO}} - \frac{1}{3} q_{\text{H}_2}$ . The case with the most extensive dissolved gas concentration gradient was subsequently used to study a wide range of industrially relevant conditions, by running simulations with varying biomass concentrations (2, 5, 7.5, 10 and 25 gL<sup>-1</sup>).

The obtained dissolved gas concentrations from the Eulerian simulations for the different biomass concentrations were compared to approximations obtained by a simple ideal-mixing model ( $c_{L,i}$  from Equation 4.8), wherein it was assumed that all transferred gas is directly consumed. The ideal-mixing model used the same parameters (Table 4.1) and uptake kinetics (Equations 4.6 and 4.7), an average pressure (274 kPa), and the volume-average  $k_L a$  obtained from the CFD simulations.

$$MTR_i = (k_L a)_i (H_i p y_i - c_{L,i}) = q_i c_x = r_i \quad (4.8)$$

## Lifeline analysis

Microbial lifelines were obtained for three cases with different biomass concentrations (5, 10 and 25 gL<sup>-1</sup>). Massless Lagrangian particles were injected at the sparger and tracked for a certain number of circulation times  $N_{t_c}$  and particles  $N_p$ . To account for turbulence effects, Fluent's discrete random walk model was enabled. While tracking the particles, the current time, position, concentrations, and biomass-specific uptake rates were stored in text format every 0.1 s. Data obtained for the first 90 s (approximately one 95% mixing time  $t_m$ , Figure C.1) were discarded to ensure that the particles were evenly dispersed over the whole reactor volume during the entire analysis.

The lifelines revealed distinct periods of maxima and minima (i.e., peaks and valleys) in both dissolved CO and H<sub>2</sub> concentrations. *Peak* and *valley* periods were defined from the lifelines by comparing the transient concentrations in the lifeline with the Eulerian average dissolved gas concentration: in case the transient concentration was 2 times (for the 5 gL<sup>-1</sup> case) or 1.5 time (for the other cases) higher or lower than the Eulerian average concentration for at least 1 s, then a peak or valley was assigned, for which the residence time and the average gas concentration were stored. Probability-normalised histograms were calculated subsequently using 100 linearly distributed bins over the whole parameter space (e.g., residence time or average concentration in peak), except for time in the valleys where the maximum value was capped at 150 s. The circulation time  $t_c$  was calculated as the average time between two peaks (Equation 4.9):

$$t_c = N_p \frac{t_{\text{lifeline}}}{N_{\text{peaks}}} \quad (4.9)$$

For the case with 5 gL<sup>-1</sup> biomass, lifelines were obtained during  $t_{\text{lifeline}} = 1000$  seconds (around 23 circulation times) and for  $N_p = 160,000$  Lagrangian trajectories. This resulted into extensive simulation time and data usage so that the analysis of the full dataset was computationally unwieldy. Therefore, we had to determine how many Lagrangian trajectories ( $N_p$ ) and circulation times ( $N_{t_c}$ ) were needed to ensure statistical independence using the Kullback-Leibler divergence (see Appendix B, Figure C.2).

## Design of a scale-down simulator

The scale-down simulator was designed based on the results of the lifeline analysis (i.e., the probability density functions of concentrations and residence times in peaks and valleys). The goal of this scaled-down system is to reproduce to the best possible degree the residence times and concentrations experienced by microbes in the full-scale system. The starting point was a continuously operated bench-scale stirred tank reactor (CSTR) (see Figure 4.1 and Table C.1), for which operational conditions were varied to mimic the large-scale environment at several biomass concentrations.

Mass transfer, dilution and consumption rates were modelled for CO, H<sub>2</sub>, CO<sub>2</sub> and biomass while assuming ideal mixing in the liquid phase (Equation 4.10). The evolution of the gas (CO, H<sub>2</sub> and CO<sub>2</sub>) composition in the dispersed phase  $y_{D,i}$  and in the headspace

$y_{H,i}$  were also considered (Equation 4.11, 4.12) since these could be highly variable during operation at low gas flow rates. The dispersed gas volume  $V_{G,D}$  was determined by approximating the gas hold-up using the method proposed by [25], while volume balancing was done to calculate the headspace gas volume  $V_{G,H}$ .

$$\frac{dc_{L,i}}{dt} = D_r(c_{L,i,\text{in}} - c_{L,i}) + (k_L a)_i (H_i p y_i - c_{L,i}) + q_i c_x \quad (4.10)$$

$$\begin{aligned} \frac{dy_{D,i}}{dt} &= \frac{F_{G,\text{in}}}{V_{G,D}} y_{i,\text{in}} - \frac{F_{G,\text{out}}}{V_{G,D}} y_{D,i} - \frac{V_L}{V_{G,D}} (k_L a)_i (c_{L,i}^{\text{sat}} - c_{L,i}) \frac{RT}{p} \\ \text{with } F_{G,\text{out}} &= F_{G,\text{in}} - \sum_{i=\text{all gases}} \left[ (k_L a)_i (c_{L,i}^{\text{sat}} - c_{L,i}) \right] V_L \frac{RT}{p} \end{aligned} \quad (4.11)$$

$$\frac{dy_{H,i}}{dt} = \frac{F_{G,\text{out}}}{V_{G,H}} (y_{D,i} - y_{H,i}) \quad (4.12)$$

The volumetric mass transfer coefficient  $k_L a$  of compound  $i$  is dependent on the superficial gas velocity and the stirrer speed [71] and was estimated by considering mass transfer enhancement by the broth composition ( $f_{\text{broth}} = 1.5$ , [206]), the temperature and the compound-specific diffusion coefficient in water (Equation 4.13). The power input was estimated for a Rushton impeller with  $P_0 = N_{\text{Po}} n^3 d_{\text{imp}}^5$  and the used geometry [25, 209].

$$\begin{aligned} (k_L a)_i &= f_{\text{broth}} \cdot \left[ 0.026 \left( \frac{P}{V_L} \right)^{0.4} (u_{G,s})^{0.5} \right] (1.022^{(T-293.15)}) \sqrt{\frac{D_{L,i}}{D_{L,\text{O}_2}}} \\ \text{with } P &= \alpha \left( \frac{P_0^2 n d_{\text{imp}}^3}{F_{G,\text{in}}^{0.56}} \right)^\beta \end{aligned} \quad (4.13)$$

The overall gas consumption rate was determined using the local concentrations in the liquid phase via Equations 4.6 and 4.7 and the biomass concentration. The total biomass growth rate ( $\mu \cdot c_x$ ) was determined using the model parameters derived by [32] for solventogenic conditions (Equation 4.14), while neglecting the maintenance requirements of the biomass. Biomass retention in the system was assumed (e.g., [31]) and varied by adjusting the biomass recycling rate  $R_{\text{rec}}$ .

$$\mu = q_{\text{CO}} Y_{x/\text{CO}} + q_{\text{H}_2} Y_{x/\text{H}_2} \quad (4.14)$$

The modelled bench-scale reactor was operated with a constant dilution rate of  $0.021 \text{ h}^{-1}$ , inlet gas flow of 0.05 vvm, temperature of  $37^\circ\text{C}$ , pressure of 101 kPa and a stirrer speed during start-up of 75 rpm. Initial concentrations of CO,  $\text{H}_2$ ,  $\text{CO}_2$  and biomass in the liquid from Table 4.2 were assumed to solve the system with the ode15s function in MATLAB. After the start-up period the concentration oscillations were repeatedly imposed by varying the stirrer speed. The obtained scale-down lifelines were analysed using the same routine as for the industrial-scale reactor but considering no threshold factor to discriminate between the peaks and valleys, since these were manually imposed.

**Table 4.2:** Parameters specifically used for the design of the scale-down simulator. The other parameters as in Table 4.1.

Name	Symbol	CO	H <sub>2</sub>	CO <sub>2</sub>	Biomass	Unit	Source

## 4.3. Results and discussion

### 4.3.1. Eulerian concentration gradients

#### Influence of gas production

The results of Eulerian simulations with  $25 \text{ gL}^{-1}$  biomass in two CO<sub>2</sub> production cases were compared in terms of the dissolved CO concentration  $c_{L,\text{CO}}$  distribution in the reactor (Figure 4.2a,b). Although the dissolved gas concentrations in both simulations were in the same range (as expected since the biomass concentration was kept constant), the spatial distribution of  $c_{L,\text{CO}}$  within the riser was completely different. In both cases, the highest CO concentrations appeared at the base of the riser, where the mass transfer rates are high due to the hydrostatic pressure and high CO and H<sub>2</sub> gas fractions. As the gas rises, the pressure and gas fractions decrease, leading to lower mass transfer rates. More mass transfer was observed in the top separator due to the locally increased gas hold-up (Figure C.3), leading to increased  $c_{L,\text{CO}}$ . In the downcomer, the long biomass residence time and poor gas renewal caused low CO concentrations.

The gas plume is pushed towards the left side by the liquid exiting the downcomer, resulting in high dissolved gas concentrations at the left side in the case without CO<sub>2</sub> production, which is due to reduced oscillations in the gas plume. When CO<sub>2</sub> is considered, the gas, and thus the dissolved syngas, concentrate towards the middle (Figure 4.2a, b) similar to the case without gas consumption [197]. Additional gas is generated halfway the riser by microbial reaction and is transferred back to the gas phase due to CO<sub>2</sub> oversaturation at decreased hydrostatic pressure. The additional gas in the riser (cf. Figure C.3a, b) leads to transport of dissolved CO towards the right side of the riser (cf. Figure 4.2a, b) and homogenises the dissolved gas distribution (i.e., the variation of  $c_{L,\text{CO}}$  and  $c_{L,\text{H}_2}$ ) within the whole reactor volume (Figure C.4).

Next to  $c_{L,\text{CO}}$ , the evolution of gas hold-up  $\varepsilon_G$  and consequently  $k_L a$  in the EL-GLR are highly affected by gas consumption (Figure 4.2c, d). As the mass transfer simulation starts without dissolved gas at  $t = 1200 \text{ s}$ , there is an initial drop in  $\varepsilon_G$  due to gas dissolution. The lower  $\varepsilon_G$  causes a drop in  $k_L a$  because of their linear dependence (Equation 4.5). After about 400 s the liquid saturates with dissolved gas and  $\varepsilon_G$  and  $k_L a$  stabilise. When the reaction is switched on at  $t = 2200 \text{ s}$ , both  $\varepsilon_G$  and  $k_L a$  suffer a significantly drop in the cases with high biomass concentration, since high amounts of gas are being consumed (Figure C.3), even when CO<sub>2</sub> production is included. Similar decreases in  $\varepsilon_G$  were also

Figure 4.2: Effect of CO<sub>2</sub> production on mass transfer and dissolved gas distribution. Time-averaged (200 s) dissolved CO concentrations  $c_{L,CO}$  in the  $zy$ -plane ( $x = 0$ ) of the EL-GLR for 25 gL<sup>-1</sup> biomass a) without CO<sub>2</sub> production and b) by considering CO<sub>2</sub> production. Time-dependence of the dispersion volume-averaged c)  $\varepsilon_G$  and d)  $k_La$  during the CFD-simulations. Until 2200 s only gas-liquid mass transfer was included (black line). At 2200 s gas consumption was switched on in the model in three cases: 2 gL<sup>-1</sup> biomass without CO<sub>2</sub> production (blue line), 25 gL<sup>-1</sup> biomass without CO<sub>2</sub> production (red line), 25 gL<sup>-1</sup> biomass including CO<sub>2</sub> production (green line).

visible in the model by Siebler et al. [56]. Interestingly, with little biomass in the reactor (2 gL<sup>-1</sup>) the gas conversion is highly decreased (from 0.67 kg s<sup>-1</sup> at 25 gL<sup>-1</sup> to 0.16 kg s<sup>-1</sup>) due to inhibiting CO concentrations (Figure C.5), increasing  $\varepsilon_G$  and  $k_La$  compared to the cases with more biomass.

Although  $\varepsilon_G$  could be well predicted with empirical relations in cases without gas consumption [197], the 33% decrease in  $\varepsilon_G$  by microbial gas consumption makes the prediction of  $\varepsilon_G$  and thus  $k_La$  even more challenging in operational EL-GLRs. This observation is especially relevant for gases rich in carbon source or electron donors, like the used syngas, in contrast to air where the dilution with inert N<sub>2</sub> and typically near equimolar conversion of O<sub>2</sub> into CO<sub>2</sub> results in negligible volume changes due to mass transfer.

The reduced gradients when considering CO<sub>2</sub> production, would decrease the impact of  $c_{L,CO}$  variations on microorganisms. Due to uncertainties on the metabolism, e.g., the possibility of simultaneous CO and H<sub>2</sub> consumption [44], the modelled cases would either under- or overestimate the CO<sub>2</sub> production rate. Since the case without CO<sub>2</sub> production appears to generate larger fluctuations and thus complicate the design of the scale-down simulator (and this is, dependent on the syngas composition, the ideal gas fermentation process from an environmental point of view), we further examined this scenario.

### Influence of biomass concentration

Dissolved gas concentration fields in the large-scale reactor were computed with 2, 5, 7.5, 10, and 25 gL<sup>-1</sup> biomass, as shown in Figure C.6 and Figure C.7. The variability that the microbes experience in dissolved CO and H<sub>2</sub> concentrations, as well as the corresponding biomass-specific uptake rates  $q_{\text{CO}}$  and  $q_{\text{H}_2}$ , are displayed in Figure 4.3.

The mean values for the Eulerian fields follow the same trend as the ideal-mixing model (Equation 4.8), indicating that the concentration range is predominantly  $c_{L,i} < K_{S,i}$ . For  $c_x$  below 5 gL<sup>-1</sup>, the high potential mass transfer capacity compared to the reaction rate leads to strong CO inhibition, while in the 5–10 gL<sup>-1</sup> range the mass transfer rate is in equilibrium with microbial syngas consumption at lower dissolved gas concentrations. At high  $c_x$  (25 gL<sup>-1</sup>) gas uptake is fast, leading to low  $c_{L,i}$  and thus also low uptake rates. This decrease in  $q_i$  is compensated by the greater  $c_x$ , causing the volumetric reaction rate and gas conversion to remain similar to cases with less biomass and higher biomass-specific uptake rates (Figure C.5). The ideal-mixing model suggests that an optimum  $q_i$  could be obtained at a certain biomass concentration, but the exact biomass concentration remains challenging to be determined using the CFD models considering the wide concentration distribution, the non-linear kinetics, and that iteratively running these models is very time-consuming. As there is less inhibition at higher  $c_x$ , there could be a possibility to increase gas conversion by supplying more gas, providing that coalescence remains suppressed by broth components [206].

There is a large volumetric spread in the dissolved gas concentrations obtained by the CFD models. The highest quartile of concentrations is often a factor 10 higher than the concentrations in the second quartile (e.g., at 5 gL<sup>-1</sup> Q2 of  $c_{L,\text{CO}}$  starts around  $1 \times 10^{-2}$  molm<sup>-3</sup>, while Q4 starts at  $1 \times 10^{-1}$  molm<sup>-3</sup>). This would imply that the microorganism could experience regular concentration fluctuations of around one order of magnitude. However, due to the non-linear nature of the CO and H<sub>2</sub> uptake kinetics, such fluctuations only lead to minor oscillations in biomass-specific uptake rates. Here, the observed concentration gradients are significantly smaller than those in sugar fermentations with similar  $\tau_{\text{rxn}}$  [57], due to the continuous gaseous substrate supply. However, the spread in the concentration fields may cause an overestimation of uptake rates by the ideal mixing models.

Overall, the ideal mixing model was able to describe the concentration range reasonably well, especially in the limitation regime, and could still be used for quick estimations of dissolved gas concentrations at varying conditions (e.g., increased mass transfer, pressure, or with different kinetics). The spatio-temporal variations in  $c_{L,i}$ , which can only be obtained by CFD modelling, are then to be estimated as  $\pm$  half-an-order of magnitude around the derived concentrations from the ideal mixing model.

**Figure 4.3:** Spatial variations in (a, b) dissolved CO and H<sub>2</sub> concentrations and (c, d) biomass-specific uptake rates, represented in boxplots, for varying biomass concentrations. The boxplots were obtained from the 200 s time-averaged results of the CFD simulations and depict the spread around the mean values, with each quartile representing 25% of the reactor volume, while the diamond symbol represents the volume-averaged mean value. The dashed line is the result of a simple ideal-mixing model, using the volume-averaged  $k_L a$  from the CFD model ( $0.050 \text{ s}^{-1}$  for CO and  $0.074 \text{ s}^{-1}$  for H<sub>2</sub>).

### 4.3.2. Lifeline analysis

From the lifelines obtained in cases with 5, 10 and 25 g L<sup>-1</sup> biomass it appears that the microorganisms could experience frequent fluctuations in solute concentrations (in 5 to 30 seconds), as visible from Video S1. To quantify the microbial experience, the residence times in the peaks and valleys of substrate concentrations were determined, as well as the average dissolved CO and H<sub>2</sub> concentration during a peak or valley. From the resulting probability density functions, we determined the joint probability of observing a specific residence time and concentration in a peak or valley (Figure 4.4).

The dynamic behaviour of the EL-GLR causes a large spread in the observed concentrations and residence time. This makes it impossible to standardise a concentration profile of a lifeline. The difference in concentration between the peaks and valleys are around a factor of 5, but within these there are significant deviations (up to 50%) around their specific mean values.

**Figure 4.4:** Scatter plots representing the likelihood of a microbe to experience peaks or valleys with a certain combination of  $c_{L,CO}$  and duration. Each dot represents a peak or valley with a concentration and residence time, and is colored by the probability of occurrence of that specific combination in the whole set of lifelines. Each row of plots represents data obtained with a specific biomass concentration: (a, b) 5, (c, d) 10 and (e, f) 25 g L<sup>-1</sup>. Peaks are in the left column of plots (a, c, e) and the valleys are at the right (b, d, f). A similar figure was made for H<sub>2</sub> (Figure C.8).

Although the average gas concentrations during the oscillations are very different for the three biomass concentrations, the microbial residence time distributions are quite similar. This is caused by the similar hydrodynamic behaviour in the three cases, resulting from similar superficial gas flow velocity and gas conversion rates while neglecting the influence of biomass concentration on fluid properties (density and viscosity). Interest-

ingly, in the cases with 5 and 10 gL<sup>-1</sup> the dips in concentration lasted sometimes very long (> 100 s). This could be due to a recirculation pattern in the downcomer. Since in the 25 gL<sup>-1</sup> case the concentration difference is small between peaks and valleys, and still some gas pockets with relative high CO concentration exist, such moments were not observed.

During the CO peaks at 5 gL<sup>-1</sup>, cells can spend short moments (between 5 and 15 s) at inhibitory concentrations (since  $K_I = 0.25 \text{ mol m}^{-3}$ ). In this case  $c_{L,\text{CO}}$  still remains around the values needed for an optimum  $q_{\text{CO}}$ , so that strong inhibition would not be expected since  $t_{\text{peak}} < t_c \approx 40 \text{ s}$ , based upon the used kinetic model. The precise microbial response to such short moments of potential inhibition is unclear.

Similar results were obtained for H<sub>2</sub> (Figure C.8). The residence times in peaks and valleys were in the same ranges as for CO, with high concentration fluctuations of about a factor 5 noticed. Because H<sub>2</sub> uptake was inhibited at a relatively low  $c_{L,\text{CO}}$  ( $K_{I,\text{CO}} = 0.025 \text{ mol m}^{-3}$ ), this resulted in high levels of CO inhibition during peaks. When interested in H<sub>2</sub> (and thus CO<sub>2</sub>) conversion, CO levels should be kept well below the inhibitory values, which could be achieved by adjusting the inlet gas composition (e.g., by green hydrogen supplementation) and/or by increasing the biomass concentration. Due to the strong fluctuations in  $c_{L,\text{CO}}$  and the inhibiting effect of CO on H<sub>2</sub> uptake,  $q_{\text{H}_2}$  was significantly influenced, highlighting the need to study the mutual effect of CO and H<sub>2</sub> fluctuations on  $q_{\text{H}_2}$ .

The ratio between the average dissolved concentrations of CO and H<sub>2</sub> ( $c_{L,\text{CO}}/c_{L,\text{H}_2}$ ) increases with an increased biomass concentration:  $c_{L,\text{CO}}/c_{L,\text{H}_2} \approx 2$  at 5 gL<sup>-1</sup>, 3 at 10 gL<sup>-1</sup> and 6 at 25 gL<sup>-1</sup>. This is caused by the faster decrease of  $q_{\text{CO}}$  compared to  $q_{\text{H}_2}$  with biomass concentration (cf. Figure 4.3 c, d) due to decreased CO inhibition. To inspect the level of inhibition by CO in the determined ranges for peaks and valleys, the biomass-specific CO and H<sub>2</sub> uptake rates were calculated for each case using its respective  $c_{L,\text{CO}}/c_{L,\text{H}_2}$  ratio (Figure 4.5).

From determining the specific gas uptake rates, it became clear that the reactor should be operated in the limitation regime, when increasing  $c_{L,i}$  would result in a greater  $q_i$  (e.g., at 25 gL<sup>-1</sup>) while inhibitory concentrations are avoided. At low biomass concentration (5 gL<sup>-1</sup>), CO inhibition is already problematic, leading to decreased H<sub>2</sub> uptake rates in the peaks. With 10 gL<sup>-1</sup> a significant increase in  $q_{\text{CO}}$  is observed when transitioning from a valley to a peak (from 0.3 to 0.8 mol mol<sub>x</sub><sup>-1</sup>h<sup>-1</sup>), but small increases in  $c_{L,\text{CO}}$  during the peaks could worsen overall performance since  $q_{\text{CO}}$  is close to optimum. From the oscillatory dataset of Mahamkali et al. [204] was derived that fluctuations in  $q_{\text{CO}}$  and  $q_{\text{H}_2}$  in the timescale of hours lead to large increases in  $q_{\text{EtOH}}$  and thus the ethanol yield [40]. Scale-down experiments with imposed concentration fluctuations could inform whether this observation holds for the circulation timescale as well.

**Figure 4.5:** Overall biomass-specific a) CO and b) H $_2$  uptake rates computed for biomass concentrations of 5 (blue), 10 (red), and 25 g L $^{-1}$  (green).  $c_{L,CO}$  in the H $_2$  uptake kinetics was calculated by using a  $c_{L,CO}/c_{L,H_2}$  of 2, 3 and 6 for each respective case. The full arrows indicate the concentration ranges of the peaks, while the dashed arrows indicate the ranges for the valleys. CO-uptake is independent of the biomass concentration, hence the single line.

4

Too low dissolved gas concentrations would cause a thermodynamically infeasible catabolism and thus no syngas uptake at all. Such concentrations were estimated to be around  $4 \times 10^{-4}$  and  $3 \times 10^{-3}$  mol m $^{-3}$  for CO and H $_2$ , respectively, assuming independent consumption of CO and H $_2$ /CO $_2$  for solventogenesis [32]. Since such low  $c_{L,CO}$  was not obtained in our analysis, we did not expect such problems for CO consumption. However, for H $_2$ , values below the thermodynamic limit were attained in the valleys for 10 and 25 g L $^{-1}$  biomass, so that a coupling with CO consumption is potentially required to supply enough electrons for H $_2$  uptake. As this may come at the expense of the product yield, further scale-down studies are required to determine how *C. autoethanogenum* may react to such short-term fluctuations in H $_2$  concentration.

Siebler et al. [56] estimated that a starvation regime could occur when  $c_{L,CO} < 3 \times 10^{-3}$  mol m $^{-3}$ . Since in this regime a major portion of the energy might be spent on maintenance catabolism, lower growth rates can be expected, leading to higher product yield. In the configuration they studied, such CO shortages were highly likely to occur, causing a probable shift towards a starvation regime. In our simulations, this situation may only occur in the valleys when operating with high  $c_x$ . Due to higher  $c_{L,CO}$  in our other cases, reaching the maintenance catabolism was very unlikely to occur, since  $k_L a$  of the EL-GLR was a factor 5 higher than in the BCR studied by Siebler et al. [56] (with  $k_L a \sim 0.01$  s $^{-1}$  and  $c_x = 10$  g L $^{-1}$ ).

Our results suggest that even higher  $c_x$  may be advantageous, considering the current operation in the limitation regime and that high mass transfer could be obtained due to bubble coalescence suppression in the fermentation broths. Operation at very low  $c_{L,CO}$  would enable operational flexibility and a high product yield, without sacrificing gas conversion. Caution is needed to prevent that the dissolved gas concentrations do not get so low that the reaction becomes thermodynamically unfeasible, or that the high  $c_x$  hampers mass transfer and mixing by increasing broth viscosity [179].

In the LanzaTech process,  $k_{L,CO}a$  could well be around 3-4 times higher [197] than the final one obtained in our model ( $650\text{ h}^{-1}$  vs.  $180\text{ h}^{-1}$ ). This could be due to mass transfer intensification (e.g., by introduction of perforated plates [20]) or by achieving smaller bubbles ( $\sim 1\text{ mm}$ ). Although bubbles would become more rigid in such a case, mass transfer might still be enhanced by cell monolayers around the bubbles, especially in case of operating at high biomass concentrations [25]. In such high mass transfer cases, substantial CO inhibition might be expected, stressing the need to operate at high ( $> 25\text{ gL}^{-1}$ ) biomass concentrations.

#### 4.3.3. Development of scale-down simulator

Based upon the analysis of the CFD data, we used numerical simulations to propose a conceptual design of a scale-down simulator to experimentally replicate the dissolved gas concentrations which were estimated to be experienced by microorganisms in the industrial-scale syngas fermentation. A single-vessel system, being a 2 L working volume CSTR, was chosen as basis for the scale-down simulator. Since rapid and irregular fluctuations in peaks and valleys should be obtained, we did not consider multi-vessel systems with forced circulation because rapid consumption of dissolved gas in the tubes connecting the vessels would be detrimental for the performance. In addition to the advantage of no substrate depletion in the tubes, clogging or high shear stress by pump action could also be avoided. In a well-mixed stirred-tank, there are little spatial variations in dissolved gas concentration (unlike plug-flow systems) so that the dissolved gas concentrations can be better controlled. Another potential scale-down system would be a two-stage STR with a perforated plate separating two well-mixed zones [210]. This way the dynamic interchange between two concentrations could be reproduced, although the step transitions might be unrealistic for the observed large-scale behaviour. A significant disadvantage of using a single-vessel is the lack of population heterogeneity in cellular experience, which would definitely be present in multi-vessel systems, as well as the poor incorporation of dead (or low concentration) zones such as the downcomer [211, 212]. Furthermore, slow mixing at low power input might possibly lead to local concentration gradients [71]. Operation at smaller scales with better mixing (e.g., 200 mL) might, however, lead to practical problems regarding sampling.

To mimic the large-scale successfully, we should make sure that the microbes experience similar peak/valley duration and concentration differences as in the large-scale bioreactor. Although we could argue from Figure 4.4 that most peaks last between 5 and 15 seconds, and valleys 10 to 30 seconds, this argument does not account for frequently occurring irregularities. There are peaks and valleys that largely exceed these times, e.g., peaks of 25 s and valleys of 60 s are not exceptional, and the scale-down simulator should replicate such outliers in terms of time and concentration. With the probability distributions of the residence times derived from the CFD lifelines, variations in the stirrer speed were imposed to obtain corresponding peaks and valleys in the scale-down simulator. It

**Table 4.3:** Operational conditions of the scale-down simulator to obtain an acceptable fit of the lifelines obtained by the scale-down simulator with the CFD-derived lifelines.

Peak				Valley			Recycle	
$c_{x,EL-GLR}$ ( $\text{g L}^{-1}$ )	$n$ (rpm)	$k_{L,CO}^a$ ( $\text{h}^{-1}$ )	$P/V$ ( $\text{W m}^{-3}$ )	$n$ (rpm)	$k_{L,CO}^a$ ( $\text{h}^{-1}$ )	$P/V$ ( $\text{W m}^{-3}$ )	$R_{rec}$ (-)	$c_{x,SD}$ ( $\text{g L}^{-1}$ )
5	910	153	23,000	20	1.3	0.11	0.5	0.54
10	900	150	2200	150	15	70	0.91	1.44
25	500	71	3400	70	5.6	6.1	0.96	3.27

was determined that around 2000 oscillations, lasting  $\sim 15$  h in total, should be applied in the scale-down simulator to make sure that enough variation in peak or valley residence time is imposed (Figure C.2). To account for the varying biomass concentrations from the three CFD cases (5, 10 and  $25 \text{ g L}^{-1}$ ), the biomass recycling rate  $R_{rec}$  was altered between the different cases to adjust the reaction rate.

With this computational set-up and the iteratively derived operational conditions (Table 4.3), lifelines were simulated in the conceptual bench-scale reactor for the three different  $c_x$  that roughly correspond to the large-scale lifelines (Figure 4.6). The pulses in stirring speed are well captured and provide the same peak-valley frequencies as is expected at the large-scale. The concentrations that the microbes would experience are similar as in the large-scale bioreactor within the peaks and valleys. For example, for CO and H<sub>2</sub> in the  $5 \text{ g L}^{-1}$  cases the upper concentrations are always in the same order of magnitude and the experienced valleys are very similar to the ones in the large-scale reactor (Figure 4.6a, b). For the cases with high  $c_x$  it is more challenging to represent the deep concentration valleys well ( $c_{L,i} \ll 1 \times 10^{-3} \text{ mol m}^{-3}$ ) since the increased  $c_x$  generally requires more mass transfer in the valleys. Since the impact of such concentrations on the  $q_i$  is small (Figure 4.5), negligible influence of this was expected.

The rate of increase in dissolved gas concentration during the transition from a valley to a peak in the scale-down simulator is very similar to that in the large-scale bioreactor: instantaneously the microbes experience concentration increases up to around 1 – 2 orders of magnitude in a matter of seconds (1 – 5 s). The decrease of the slope at the beginning of the peaks in  $c_{L,CO}$  can equally be identified in some of the peaks of the CFD lifelines. In the large-scale this rapid increase is due to the microorganism travelling instantly into a zone with high mass transfer and thus dissolved gas concentrations, while in the scale-down simulator the mass transfer increase responds to the step increase in stirring speed.

The transition from the peak to the valley was found to be more problematic to reproduce in the bench-scale reactor for the cases with 10 and  $25 \text{ g L}^{-1}$ . Although the dissolved gas concentration decay is more plug flow-like at the large-scale, immediate decreases back to a representative "valley-baseline" were observed in the scale-down simulator. Simulating a ramped decrease in stirring speed could be helpful to obtain a more realistic decay in concentrations.

Figure 4.6: Microbial lifelines obtained from the simulation of the EL-GLR (blue) and the scale-down simulator (red), for CO and H<sub>2</sub>, and the varying biomass concentrations in the large-scale reactor: a, b) 5 gL<sup>-1</sup>; c, d) 10 gL<sup>-1</sup>; e, f) 25 gL<sup>-1</sup>. Random lifelines were chosen from the CFD simulation (blue) and a random time span of the lifelines in the scale-down simulator

A major factor varying between the two scales is the frequency and magnitude of cellular exposure to shear forces. This was quantified with the energy dissipation/circulation function ( $EDCF = \frac{P_{\text{total}}}{V_{\text{eff}}} \frac{1}{t_c}$ ) [213, 214] while approximating  $t_c$  as  $\frac{1}{4} t_m$  [71]. In the scale-down simulator there is highly varying exposure to shear between peaks and valleys when the cells are close to the impellers ( $EDCF$  varies from  $50 \text{ kW m}^{-3} \text{ s}^{-1}$  to  $1 \times 10^{-4} \text{ kW m}^{-3} \text{ s}^{-1}$ , respectively). In the EL-GLR there is only a high shear region around the gas plume ( $EDCF \sim 0.06 \text{ kW m}^{-3} \text{ s}^{-1}$ ), without considering bubble burst. The significantly varying  $EDCF$

**Figure 4.7:** Comparison of the probability density functions obtained by the scale-down simulator (bars) with the CFD results (lines). Probability density functions for a) the concentration of dissolved CO during the peaks (blue) and the valleys (red), as well as the residence time in b) valley or c) peak. Here, the case of CO with 5 g L<sup>-1</sup> biomass is provided, other cases (H<sub>2</sub> 5 g L<sup>-1</sup>, and both compounds for 10 and 25 g L<sup>-1</sup>) are provided in Figures C.10-C.14. The scale-down simulator was operated with 2000 peaks.

between two scales could be of impact when *C. autoethanogenum* is shear-sensitive, but this was not expected, due to its small size (around 3  $\mu\text{m}$ ) compared to the Kolmogorov scale ( $\sim 10 \mu\text{m}$ ) [4, 215].

The correspondence of the results of the scale-down simulator with the large-scale reactor was determined by performing a lifeline analysis. In this way, the probability distributions for the residence times and the concentrations in the peaks and valleys could be compared quantitatively (Figure 4.7 and Figures C.10-C.14). Generally, a very good correspondence of the residence time distributions was obtained. To some extent this is logical as CFD results of these are the inputs of the scale-down simulator, although the limitations of a bench-scale reactor do not guarantee good correspondence to be feasible; it indicates the feasibility of imposing rapid stirring speed fluctuations in a well-mixed bench-scale system.

Corresponding concentration distributions were more challenging to obtain since the ranges of the large-scale CO peak concentrations are very large (0.1 – 0.25  $\text{mol m}^{-3}$ , Figure 4.7a). In the scale-down simulator the CO peak concentration could not become that high (maximum 0.2  $\text{mol m}^{-3}$ ) so that a narrower range was obtained, which was more skewed towards the lower concentrations. The assumptions and parameters used in the mass transfer and kinetic models make it challenging, however, to purely rely on

quantitative results for the concentration fluctuations in the scale-down setup. Using more accurate mass transfer and kinetic models would increase the reliability of our quantitative predictions and thus our conceptual scale-down simulator.

Despite all these limitations, we showed that with a conceptually relatively simple scale-down simulator, the large-scale dissolved gas concentration gradients for a wide range of biomass concentrations could be reproduced in lab-scale. Model-based tuning of the operational conditions (e.g., stirrer speed, gas flow rate, gas composition) of the scale-down set-up on the probability distribution functions of the large-scale reactor, is a possible strategy to maximise correspondence between the two scales and thereby provide a fruitful basis towards representative scale-down of syngas fermentation.

#### 4.3.4. Outlook

Further improvement of the scale-down simulator could lead to even better representations of the large-scale behaviour. An optimisation routine could help obtaining the best-fit parameters with the CFD-derived data. The ideal scale-down simulator has as few as possible variable parameters and represents the large-scale behaviour for a wide range of conditions. The effect of parameters (e.g., stirrer speed during the start-up phase) could be derived using tools such as principal component analysis during the optimisation and help deciding whether or not to use the parameter in further analyses.

The quantitative results of the CFD study and the proposed scale-down study are strongly dependent on the process conditions (e.g., headspace pressure, gas fraction) as well as on the kinetic model for CO and H<sub>2</sub> uptake. For example, the current models for CO-uptake significantly underestimate the maximum specific growth rate ( $\mu_{\text{model}}^{\text{max}} = 0.03 \text{ h}^{-1}$ ) compared to experimental values ( $\mu_{\text{exp}}^{\text{max}} = 0.12 \text{ h}^{-1}$ ) [45]. As they are parameterised using insufficient data, the accuracy of our simulations is decreased and is therefore a major drawback of the study. Development of accurate kinetic models is crucial for reliably modelling bioreactors, and we hope that our work motivates further research in this area. The MATLAB scripts describing the conceptual scale-down simulator are openly available and can be used for further development with updated sub-models.

Despite the mentioned limitations, the proposed set-up and method are still applicable to a wide range of conditions. Even without using CFD, but an ideal mixing model (Equation 4.8), one can estimate the effect of process variables (e.g., increased mass transfer rates) on the average concentration in the large-scale reactor. In case the reactor is operated in the gas limitation regime ( $c_{L,i} < K_{S,i}$ ), spatial concentration differences of a factor 5 around the mean could be expected based upon our CFD simulations. Since in the scenarios with varying biomass concentrations the residence time distributions in the peaks and valleys does not greatly differ, such differences are neither expected in other operational cases in the limitation regime. A scale-down simulator could then be tuned based upon the estimated concentration differences and the residence time distributions.

Although the developed scale-down simulator is conceptually easy to understand, the practical installation and operation might be challenging. The repeated variations in stirrer speed at high frequencies should be controlled, as well as possible ramp phases when increasing or decreasing the stirring speed. Ideally, rapid-sampling and/or online measurement for CO and H<sub>2</sub> [216, 217] should be applied to make sure that peaks and valleys are obtained in the intentioned manner. As the peaks and valleys are applied in the second-timescale, probe lag should be taken into account when analysing the experimental data. Furthermore, the influence of broth components on  $k_La$  in real fermentations should be considered for better predictions [206]. If the *in situ* concentrations cannot be measured, they could be predicted using a precisely determined  $k_La$  [218].

## 4

Our conceptual scale-down simulator makes it possible to simulate a statistically representative lifeline of the EL-GLR within a fraction of the time that it would cost for the CFD model to be run and analysed. Such a lifeline could then be used to study interactions between the extra- and intracellular environment by coupling with a metabolic kinetic model [40]. The obtained response should then be similar to the large-scale response due to the correspondence of both lifelines. By making variations of such lifelines, the peak and valley residence time and concentration distributions can be obtained that could lead to a desired large-scale response (e.g., high ethanol specificity).

Ramp and feast-famine studies in the scale-down set-up could be used to parameterise kinetic models that describe the short-term response of *C. autoethanogenum* [40, 94, 219], by rapid sampling of metabolite and enzyme concentrations. Ramp studies would be helpful to determine whether the instantaneous electron supply in the peaks would indeed lead to increased ethanol production, as was expected from long-term oscillations [204]. If the gas uptake rates are product-independent, then such scale-down simulators could be used for engineered strains to produce higher-value products [9], proteins [220], or for coupled reactions with other microorganisms, such as chain-elongators [221] or PHA production [222]. With the scale-down simulator, the microbe could be adapted to large-scale conditions, so that less scale-up problems might be expected [62].

The analyses of the industrial syngas fermentation process in this and our previous study [197] are all model-based and only slightly tuned based upon the scarcely available literature data of the full-scale LanzaTech operation [8, 10, 111]. To advance the syngas fermentation process, for model validation and the execution of highly representative scale-down simulators, the publication of real industrial data would be required, such as large-scale circulation times, operational  $k_La$  values, a range of dissolved gas concentrations and their gradients. All of this could, for example, enable the utilisation of a broader range of gas compositions, the development of processes towards higher-value products and intensified fermentation equipment.

In our analyses we showed that high biomass concentrations (e.g.,  $c_x > 10 \text{ gL}^{-1}$ ) might be advantageous for both product yield and gas conversion. Since the highest reported biomass concentration in syngas fermentation reactors is around  $9 \text{ gL}^{-1}$  [31],

experiments should target the influence of increased biomass concentrations and its viability on gas uptake, broth viscosity and mass transfer. The precise operating interval in terms of dissolved gas (CO and H<sub>2</sub>) concentrations should be retrieved experimentally, so that the thermodynamically infeasible range can be avoided while operating in the maintenance-dominated regime which would enable high product-to-substrate yields. Our results show that with the currently used syngas composition (20% H<sub>2</sub>) and high biomass concentration (25 gL<sup>-1</sup>), H<sub>2</sub> catabolism may be thermodynamically infeasible, although co-consumption with CO might occur [46]. Thus, in a future with intermittent green hydrogen supply from renewable resources [223], supplementation of hydrogen might be a good option to valorise excess electricity and increase the CO-to-product yield.

## 4.4. Conclusion

The effect of the biomass concentration and dissolved gas concentration fluctuations in large-scale syngas fermentation was studied with Euler-Lagrangian simulations. Based upon these numerical simulations we recommend the industrial operation at relatively high biomass concentrations, as this would reduce the effects of CO inhibition, could increase the product yield and would provide high operational flexibility. Simulations indicate that in large-scale syngas fermentation *C. autoethanogenum* will experience frequent oscillations (peaks and valleys) in dissolved gas (CO, H<sub>2</sub>) concentration of about one order of magnitude, in a timescale of seconds (5 to 30 s). Such concentration fluctuations may occur irrespective of the biomass concentration and were hypothesised to favour the ethanol yield.

The large-scale concentration fluctuations should be simulated during small-scale experiments to study how *C. autoethanogenum* adapts to industrial-scale conditions. We proposed a single-vessel scale-down simulator that theoretically replicates the fluctuations in dissolved gas concentrations by varying the stirrer speed based on the large-scale oscillations. Numerical analysis shows that the duration of the oscillations could be replicated well, but the settings might be adjusted to achieve higher similarities for the variations in concentration. The obtained lifelines in the proposed scale-down simulator represent the large-scale reactor well for a wide range of biomass concentrations and operational conditions.

Puiman, L., Almeida Benalcázar, E., Picioreanu, C., Noorman, H. J., & Haringa, C. (2024). High-resolution computation predicts that low dissolved CO concentrations and CO gradients promote ethanol production at industrial-scale gas fermentation, *Biochemical Engineering Journal*, 109330.

## Abstract

Gradients in dissolved gas concentrations are expected to affect the performance of large reactors for anaerobic gas ( $\text{CO}$ ,  $\text{H}_2$ ,  $\text{CO}_2$ ) fermentation. To study how these gradients, and the dissolved gas concentration level itself, influence the productivity of the desired product ethanol and the product spectrum of *C. autoethanogenum*, we coupled a CFD model of an industrial-scale gas fermentor to a metabolic kinetic model for a wide range of metabolic regimes. Our model results, together with literature experimental data and a model with constant dissolved gas concentrations, indicate high ethanol specificity at low dissolved  $\text{CO}$  concentrations, with acetate reduction to ethanol at very low dissolved  $\text{CO}$  concentrations and combined ethanol and acetate production at higher  $\text{CO}$  concentrations. The gradient was predicted to increase both the biomass-specific ethanol production rate and the electron-to-ethanol yield by  $\sim 25\%$ . This might be due to intensified ferredoxin and  $\text{NAD}^+$  redox cycles, with the rate of the Rnf complex - a critical enzyme for energy conservation - as key driver towards ethanol production, and all at the expense of a reduced flux to acetate. We present improved mechanistic understanding of the gas fermentation process, and novel leads for optimisation and fundamental research, by coupling observations from various down-scaled lab experiments to expected microbial lifelines in an industrial-scale reactor.

## 5.1. Introduction

In the last few years, anaerobic gas fermentation (with CO, H<sub>2</sub> and/or CO<sub>2</sub> gas mixtures) has successfully been commercialised by the company LanzaTech for the production of ethanol from industrial waste streams [8, 10]. Ethanol is the product of main interest, since it has an established use as fuel and because it can be upgraded to plastics, textiles, and fine chemicals, while the spent microbial biomass can be used as animal feed [8–11]. The industrial gas fermentation process with the acetogen *Clostridium autoethanogenum* is deployed in external-loop gas-lift reactors (EL-GLR), which has shown potential for achieving high gas-to-liquid mass transfer rates, at least in part due the coalescence-inhibiting properties of the produced ethanol [197, 206].

In large-scale bioreactors (e.g., the mentioned EL-GLR of ~500 m<sup>3</sup>), gradients in (amongst others) liquid-phase substrate and dissolved gas concentrations are usually expected when the characteristic time of consumption is smaller than those of liquid circulation and mass transfer, respectively [48, 49]. Moreover, variations in hydrostatic pressure and the gas composition were estimated to result in a gradient of factor 35 [224]. The temporal fluctuations that microorganisms experience as a consequence of these spatial gradients (*lifelines*) were found to enlarge population heterogeneity [97, 98, 202], and often lead to reduced performance [51–53].

Recent works show that spatial dissolved gas concentration gradients are also expected in industrial-scale gas fermentation bioreactors, such as bubble columns [55, 56] and the EL-GLR [224]. From the microbial perspective, the spatial concentration variations in the EL-GLR were predicted to result in frequent and irregular (5–30 s) cycles in dissolved gas (CO, H<sub>2</sub>) concentrations with one order of magnitude [224]. Long periods (> 70 s) at low CO concentrations ( $c_{L,CO}^{crit} < 0.003 \text{ mol m}^{-3}$ ) were hypothesised to result into a starvation regime, with transcriptional changes as consequence, and reduced growth rates and product yields [56].

The impact of the concentration gradient on the cellular metabolic activity, and thus its product formation rate, can be studied by coupling a computational fluid dynamics (CFD) model of a bioreactor with a dynamic metabolic model (cellular reaction dynamics, CRD), in an Euler-Lagrangian computational framework. With a one-way coupled approach and kinetics applied to the Eulerian field, the impact of the concentration gradient on the microbial metabolism can relatively quickly be assessed, while with full Euler-Lagrangian two-way coupling the microbial metabolism also impacts the gradient. The first two-way coupled simulations for industrial fermentations were performed by Reuss and co-workers [58, 98], after which follow-up work was done via various methodologies: Morchain et al. [96] used population balance models for microorganisms, while Haringa et al. [99] used a 9-pool dynamic kinetic model [94]. One-way coupled simulations for bubble column reactors were done for *Saccharomyces cerevisiae* [225] and *C. autoethanogenum* [56, 224], and it was found that microorganisms in bubble columns typically experience shorter starvation periods than in stirred-tank reactors [226]. One

of the major limitations of this approach is the computational power required for the high-resolution simulations, which can partially be relieved with the use of compartment models [205, 227, 228]. In recent years, the CFD-CRD modelling approach gained widespread attention, as it opens avenues towards more rational scale-up and optimisation of industrial-scale bioreactors [63, 66, 68].

The metabolism of acetogens and the Wood-Ljungdahl pathway have extensively been described before [11, 229, 230]. Carbon (CO and CO<sub>2</sub>) is fixed via the Wood-Ljungdahl pathway, which contains two branches: In the carbonyl branch CO is converted into CO<sub>2</sub> to reduce ferredoxins with the reversible carbon monoxide dehydrogenase (CODH) enzyme, while in the methyl branch CO<sub>2</sub> is converted into formate, which is further reduced to an activated methyl group. CO and the methyl group are then combined into acetyl-CoA at the expense of 1 ATP, which is recovered downstream through acetate production [229]. By the establishment of a chemiosmotic gradient, ATP for growth and maintenance is produced: The Rnf complex exports protons via electron transfer from reduced ferredoxin (Fd<sub>red</sub><sup>2-</sup>) to NAD<sup>+</sup> [230, 231]. Ethanol is mainly produced via the AOR pathway (named after the enzyme acetaldehyde:ferredoxin oxidoreductase), which is thermodynamically feasible only when the intracellular acetate concentration passed the threshold of 1000 times the acetaldehyde level [232, 233]. High intracellular acetate concentrations are obtained at low extracellular pH (5.0) and high concentrations of undissociated acetic acid, since this neutral form of the acid can passively diffuse into the cell [233]. H<sub>2</sub>-uptake relates to ethanol production, as its electrons are directly stored in Fd<sub>red</sub><sup>2-</sup> and NADPH [45, 46].

A 12-pool CRD model was recently developed that could describe metabolic dynamics upon metabolic-induced self-oscillations [204] of *C. autoethanogenum* in a chemostat culture [40]. This model could explain how extracellular concentrations (of CO, H<sub>2</sub>, CO<sub>2</sub>, protons and the products acetic acid, ethanol and 2,3-butanediol), and the intracellular carbon (formate, acetyl-CoA, acetate) and electron pools (Fd<sub>red</sub><sup>2-</sup>, NADH, NADPH), change upon fluctuations in any of these. From the self-oscillating culture, it was found that the biomass-specific ethanol production rate,  $q_{\text{EtOH}}$ , varies proportionally to the uptake rate of the electron donors (CO and H<sub>2</sub>) [40]. By varying the redox potential among several batch cultures Grimalt-Alemany et al. [234] observed severe dynamics (within one order of magnitude) in the NAD(H) pool size and the NADH/NAD<sup>+</sup> ratio, and that dynamics in the latter positively correlated with the ethanol specificity.

Since the observed dynamics in both studies (in the order of days) are of metabolic origin (no proteomic differences were observed in [204]) and related to thermodynamics, they may help identify how the short-timescale dynamics occurring in the industrial-scale bioreactor (in the order of seconds) affect the metabolism. Based on the dynamics in these experimental studies, we hypothesise that the temporal-variations in dissolved gas concentration as occurring in the industrial-scale EL-GLR, lead to increased  $q_{\text{EtOH}}$ , compared to a spatially- and temporally homogeneous environment.

In this work, we coupled the CRD model [40] with our previously developed CFD model of an industrial-scale EL-GLR [197, 224] supplied with a gas mix containing 50% CO, 20% H<sub>2</sub> and 30% CO<sub>2</sub>, to study how the dissolved gas concentration and its gradient may influence the metabolic behaviour of *C. autoethanogenum* (with focus on the product spectrum, substrate inhibition, and energy conservation mechanisms). Computations were done with several biomass concentrations to study a wide range of fluctuations on dissolved gas concentrations, from conditions with excess mass transfer to severe mass transfer limitations (from over-reduced to significantly under-reduced conditions). By comparing the CFD-CRD model results with those of a model with constant dissolved gas concentrations, the impact of the dissolved gas concentration and its dynamics on the metabolism and product spectrum of *C. autoethanogenum* could be studied. From the results, we could identify which metabolite pools, reactions and enzymes relate to ethanol production, establish several hypotheses for further research, and propose ways for reactor, strain and process optimisation.

## 5.2. Methods

### CFD-CRD coupling approach

The CFD model (geometry, flow pattern and operation conditions) of an external-loop gas-lift reactor ( $\sim 500 \text{ m}^3$ ) that was developed in our previous study [197], was complemented with a mass transfer model in [224], and, in the present work, with the CRD model developed in [40]. The hydrodynamic model was validated on pilot-scale data, while mass transfer rates of the EL-GLR corresponded with industrial standards by assuming bubbles with a constant diameter of 3 mm [197], possible due to coalescence inhibition [206].

The CFD simulation including black-box kinetics (with  $5 \text{ g}_x \text{ L}^{-1}$ ) and gas-liquid mass transfer, described in [224], was used as an initial condition for the CFD-CRD model described here. 250,000 Lagrangian particles were released at  $t = 3000 \text{ s}$ , and mixed for 200 s, to ensure a homogeneous distribution of particles in the reactor at the start of the CFD-CRD simulation. The pH was kept constant at 5.0, while the initial external product and intracellular metabolite and co-factor concentrations were in the range of the ones used for the CRD model calibration [40, 204] (Table D.1).

As soon as the CRD model was activated, two-way reaction coupling was applied for CO, H<sub>2</sub> and CO<sub>2</sub> according to the method described in Haringa et al. [78, 235], so that the metabolic-kinetic model determines the concentration fields and the gas hold-up. A schematic overview of the model structure and solving procedure is provided (Figure 5.1).

The development and parameterisation of the metabolic kinetic model are described extensively in [40] and the relevant parts for two-way coupling in Appendix D.1.1. The MATLAB model, comprising 12 metabolite pools and 12 reactions, was rewritten into C code, and implemented in an Euler-Lagrangian framework using the DPM\_SCALAR\_UPDATE macro in Ansys FLUENT. This allowed tracking and updating of particle-associated variables, specifically the metabolite concentrations, at every particle time step  $\Delta t_p$ , that was equal or smaller than the flow time step ( $\Delta t_p \leq \Delta t_f = 5 \text{ ms}$ ).

Since NADH has the lowest turnover time ( $\sim 1 \text{ ms}$ ) the metabolic equations were integrated with a fixed – intracellular – time step  $\Delta t_{IC}$  of 0.1 ms. As  $\Delta t_{IC} \ll \Delta t_p$ , an integration routine was implemented using the Runge-Kutta 4<sup>th</sup> order algorithm. After each  $\Delta t_{IC}$ , the concentration vector was updated until  $\Delta t_p$  was completed. The particle position was updated, while the CRD model was integrated again, until the Eulerian time step  $\Delta t_f$  had been completed. At  $t + \Delta t_p$ , the volumetric source terms for CO, H<sub>2</sub>, and CO<sub>2</sub> were computed for each particle within each volume element (VE) during the time step  $\tilde{r}_i(p, \Delta t_p)$  using the concentration differences in that particle (Equation 5.1). It was assumed that the amount of Lagrangian particles for which the CRD model was solved,  $N_p$ , are evenly distributed in the EL-GLR and that each particle equally contributes to the total biomass concentration. After  $\Delta t_f$  the volumetric source terms for the dissolved species mass balances were computed per VE by summation over each particle and the number of  $\Delta t_p$  required to reach  $\Delta t_f$ .

**Figure 5.1:** Overview of the CFD-CRD model and its solving procedure. a) Geometry of the EL-GLR wherein the equations for flow, turbulence and mass transfer are solved, together with the displacement of Lagrangian particles. b) Structure of the metabolic-kinetic model, taken from [40]. c) Step wise solving procedure of the CFD-CRD model.

$$r_{i,VE} = \frac{\sum_{p=1}^{N_{p,VE}} \sum_{\Delta t_p} \Delta t_f \tilde{r}_i(p, \Delta t_p)}{V_{L,VE}} \quad \text{with} \quad \tilde{r}_i(p, \Delta t_p) = \frac{c_i|_{t+\Delta t_p} - c_i|_t}{\Delta t_p} \frac{V_{L,reactor}}{N_p} \quad (5.1)$$

The metabolic model is based on lin-log kinetics, which is a good approximation of typical hyperbolic kinetics close to a given reference state [236, 237], but leads to inaccurate and unstable behaviour in extreme regions [236, 238]. Thus, results obtained with lin-log based metabolic models are most accurate within a rather narrow range of concentrations (typically one order of magnitude around the reference state). Such behaviour could therefore be expected when the CRD model is solved outside its range of calibration, for example at very low dissolved gas concentrations ( $c_{L,CO} < 0.025 \text{ mol m}^{-3}$ ). As wide concentration ranges occur in the large-scale reactor, several modifications have been made to the solving procedure of the metabolic-kinetic model to increase solution stability (Appendix D.1.2). This comprises rate reversibility and a rate-limitation mechanism based on a given set of minimum concentrations  $c_{i,min}$ , preventing unrealistic rates and negative intracellular concentrations.

### Model convergence and solution

5

During  $\Delta t_p$  the metabolite concentrations get updated, while the mass balances of the extracellular gas species only get updated after solving one flow time step  $\Delta t_f$ . As we assumed  $c_{i,IC} = c_{i,EC}$  for the gases, their extracellular concentrations should be updated as often as possible to preserve the mass balances, requiring very short  $\Delta t_f$ . This implies that the integrated gas uptake rate of a particle during  $\Delta t_p$ ,  $r_{i,p} = \frac{c_{i|t+\Delta t_p} - c_{i|t}}{\Delta t_p}$ , should be equal to the derivative at the beginning of that time step,  $r_{i,p} = \left. \frac{dc_i}{dt} \right|_t$  (Equations D.3-D.5). As the flow time step directly affects the total simulation duration, we set  $\Delta t_f$  to 5 ms, a compromise between simulation accuracy and computational efficiency;  $N_p$  was fixed at 80,000 on similar grounds (Appendix D.1.5, Figures D.3, D.4).

The CFD-CRD model was solved for 1000 s flow time using Ansys Fluent 2021R2 for three biomass concentration cases, with  $c_x$  of 100, 150 and  $200 \text{ mol m}^{-3}$  (2.5, 3.75 and  $5 \text{ g L}^{-1}$ ). Computations were done using the Snellius supercomputer with 128 cores of AMD Rome 7H12 CPU's, with an estimated simulation duration of 530 h per case.

Carbon and electron balance closure (relative error < 5%) for the lifelines were checked for model verification after completion of the CFD-CRD simulations. This was done for *i*) the original, unmodified ("raw"), CRD model (model  $\alpha$ ), *ii*) the CRD model with rate-limiting modifications (model  $\beta$ ), and *iii*) by not considering the values obtained for  $c_{L,CO} < 0.025 \text{ mol m}^{-3}$  (model  $\gamma$ ).

### Post-processing

The following data was exported from FLUENT every 75 ms: the concentrations of each metabolite pool, the  $q_i$  of  $\text{CO}$ ,  $\text{H}_2$ ,  $\text{CO}_2$ , acetate and ethanol, and the position and the local number of particles  $N_{p,VE}$  were written (for 4000 particles, to prevent excessive data transport and storage). With this data, concentration profiles, derivatives and rates could be reconstructed by solving the CRD model for each moment in time in MATLAB, this approach was checked by additionally writing the derivatives for 20 particles. Lifeline

data was analysed after removing the first 100 s (approximately one 95% mixing time). For visualisation, the data was smoothed using MATLAB's `smoothdata` function, according to the moving mean algorithm with smoothing factor of 0.05.

Average particle metabolite concentrations and their derivatives were stored in every VE, according to a rolling-average routine. The number of particles that was present in each VE was registered and used to calculate the rolling average of these variables.

### Model with constant concentrations

In order to determine the actual influence of the concentration gradients in the CFD-CRD model, the CRD model was also solved at constant dissolved gas concentrations. This was done for a wide range of fixed dissolved CO and H<sub>2</sub> concentrations. The CO concentration range was determined from the lifeline averages for each  $c_x$ , while  $c_{L,H_2}$  was found to be correlated to  $c_{L,CO}$  and determined via linear regression (Figure D.6); the CO<sub>2</sub> concentration was kept constant (Table D.4). The model was integrated with the same Runge-Kutta scheme as the CFD-CRD model, resetting the dissolved gas concentrations after each  $\Delta t_{IC}$  of 0.1 ms. The CRD model was solved for an interval of 1000 s (~1.5 min per simulation). This duration of 1000 s was chosen to be comparable with the CFD-CRD simulations, even if after this time the metabolism does not reach steady state.

### 5.3. Results and discussion

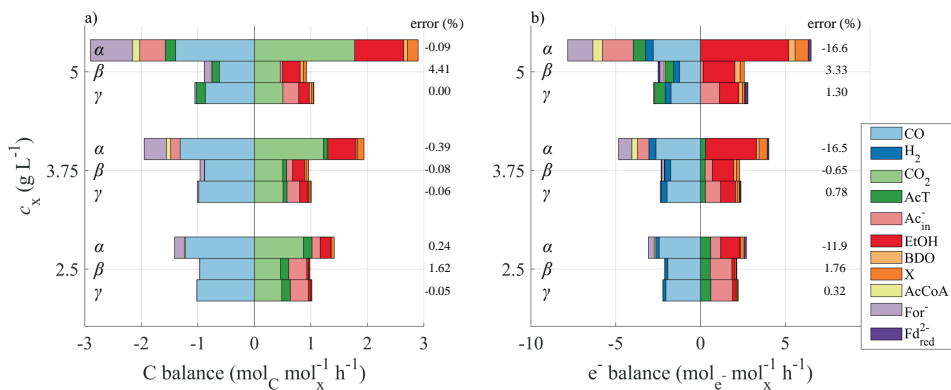

The results of our modelling study are presented first in terms of mass- and electron balances, to check the influence of the model modifications (section 5.3.1). We look into the global reactor performance, in sections 5.3.2-5.3.4, by analysing energy conservation, characteristic times and averages of individual lifelines. Then in section 5.3.5, we zoom in to discuss the metabolic behaviour and the role of key cellular reactions (particularly the Rnf complex). Several hypotheses that emerged from the study are discussed in section 5.3.6, while in the last section, 5.3.7, practical recommendations are provided for further optimising gas fermentors.

#### 5.3.1. Mass balances in the biomass phase

After solving the CFD-CRD model, we examined mass- and electron balance closure for various model modifications (Figure 5.2). This analysis reveals that the electron balance never closed for the unmodified CRD model ( $\alpha$ ), with gaps of 10 to 20%. Implementation of the rate-limiting mechanism (model  $\beta$ ) damped excessive rates (most prominently in  $J_{FDH}$ ,  $J_{CODH}$ ,  $J_{EIS}$  and  $J_{Rnf}$ ). The mechanism ensured mass balance closure (within 5%) and resulted in a substantial reduction in  $q_{EtOH}$  from  $0.4 \text{ mol mol}_x^{-1} \text{ h}^{-1}$  to a more realistic  $0.15 \text{ mol mol}_x^{-1} \text{ h}^{-1}$ .

The lin-log structure of the CRD model induced a numerical depletion of formate, at concentrations outside the range of calibration (Figure D.5). The rate-limiting mechanism dampens the formate depletion (cf. model  $\alpha$  with  $\beta$ ), although it could not entirely be avoided, due to the high minimum concentration that was required to solve the formate pool ( $10^{-4}$  vs.  $<10^{-8} \text{ mol m}^{-3}$  for other metabolites). As the rate-limiting modifications were only activated at low  $c_{L,CO}$ , the numerically generated formate escalated ethanol production rates ( $q_{EtOH}$  increased from 0.09 to  $0.15 \text{ mol mol}_x^{-1} \text{ h}^{-1}$ , cf.  $\beta$  and  $\gamma$ ). This results in uncertainty in the model predictions in the low CO concentration range. As both direct  $\text{CO}_2$  reduction to formate ( $\text{CO}_2 + \text{H}_2 \longrightarrow \text{For}^- + \text{H}^+$ ) [239], and a formic acid import and formate export mechanism were not included in the CRD model, and as net  $\text{CO}_2$  consumption was never observed, inclusion of these reactions in future work could improve the physical reliability of the model at lower  $c_{L,CO}$ .

Irrespective of the used model, clear trends in the rates were observed: for example, at increased  $c_x$  higher  $q_{EtOH}$  was observed at the expense of acetate production ( $\text{Ac}_{IC}^- + \text{AcT}$ ), while this was partly due to extracellular acetate consumption at increased  $c_x$ . As substantial parts of the reactor are operated under low CO conditions, removal or modification of these values from the lifelines would severely affect the magnitude and interpretation of the lifeline results. We hence proceed with model  $\beta$  in further analyses, considering the uncertainty in the model results at low CO concentrations.

**Figure 5.2:** Influence of the CRD model choice on the balances (denoted via metabolic rates) of post-processed lifelines. The a) carbon and b) electron mass balances are provided for the three  $c_x$  cases with the  $\alpha$ : unmodified CRD model;  $\beta$ : CRD model with rate-limiting modifications;  $\gamma$ : model  $\beta$  applied for  $c_{L,CO} > 0.025 \text{ mol m}^{-3}$ . These low  $c_{L,CO}$  occurred in all  $c_x$  cases (62% of data at  $5 \text{ g L}^{-1} < 0.025 \text{ mol m}^{-3}$ , 29% at  $3.75 \text{ g L}^{-1}$  and 10% with  $2.5 \text{ g L}^{-1}$ ). Metabolic rates (colouring in legend) were averaged for 4000 lifelines during 900 s and balanced according to their respective carbon and electron contents. The relative mass balance error was calculated via the difference between the sum of positive and negative rates (as %).

### 5.3.2. Spatial distribution of energy conservation

In line with the gas hold-up profile in the EL-GLR, there is a clear spatial gradient in dissolved CO concentration,  $c_{L,CO}$ , of around one order of magnitude between the high and low concentration zones (Figure 5.3a,b). Similar  $\varepsilon_G$  and  $c_{L,CO}$  distributions were obtained in our previous study with Haldane-type CO-uptake kinetics [224], indicating that such simulation results are largely insensitive to the model choice. High  $c_{L,CO}$  is observed in locations with high  $\varepsilon_G$ , such as in the gas plume that is being pushed towards the left side due to the liquid flow exiting the downcomer, and in the gas plume that tends to converge towards the middle of the column. A small  $c_{L,CO}$  pocket is present in the downcomer, due to some gas accumulation. The  $c_{L,CO}$  we derived is still significantly higher than the ones reported in [56] due to the severe mass transfer limitations that were adopted in their simulations ( $k_L a \approx 40 \text{ h}^{-1}$ , here  $360 \text{ h}^{-1}$ ).  $q_{CO}$  follows  $c_{L,CO}$  (Figure 5.3b,c) since uptake inhibition related to  $c_{L,CO}$  was not predicted by the CRD model (see sections 5.3.2 and 5.3.5).

Near the sparger, with locally high  $c_{L,CO}$  and  $q_{CO}$ , high rates of ferredoxin reduction are observed (Figure 5.3d). This indicates that our model predicts fast uptake (by diffusion) and utilisation of the incoming CO by CODH, and thus rapidly varying ferredoxin reduction rates, as was hypothesised [240] and measured before [241]. Higher up in the riser,  $c_{L,CO}$  and  $q_{CO}$  are still high, but moderate reduction and oxidation rates are observed since the cells might be saturated with  $\text{Fd}_{\text{red}}^{2-}$ . At zones with low  $c_{L,CO}$  and  $q_{CO}$  (downcomer, in the riser near the downcomer outlet, and close to the walls near the top

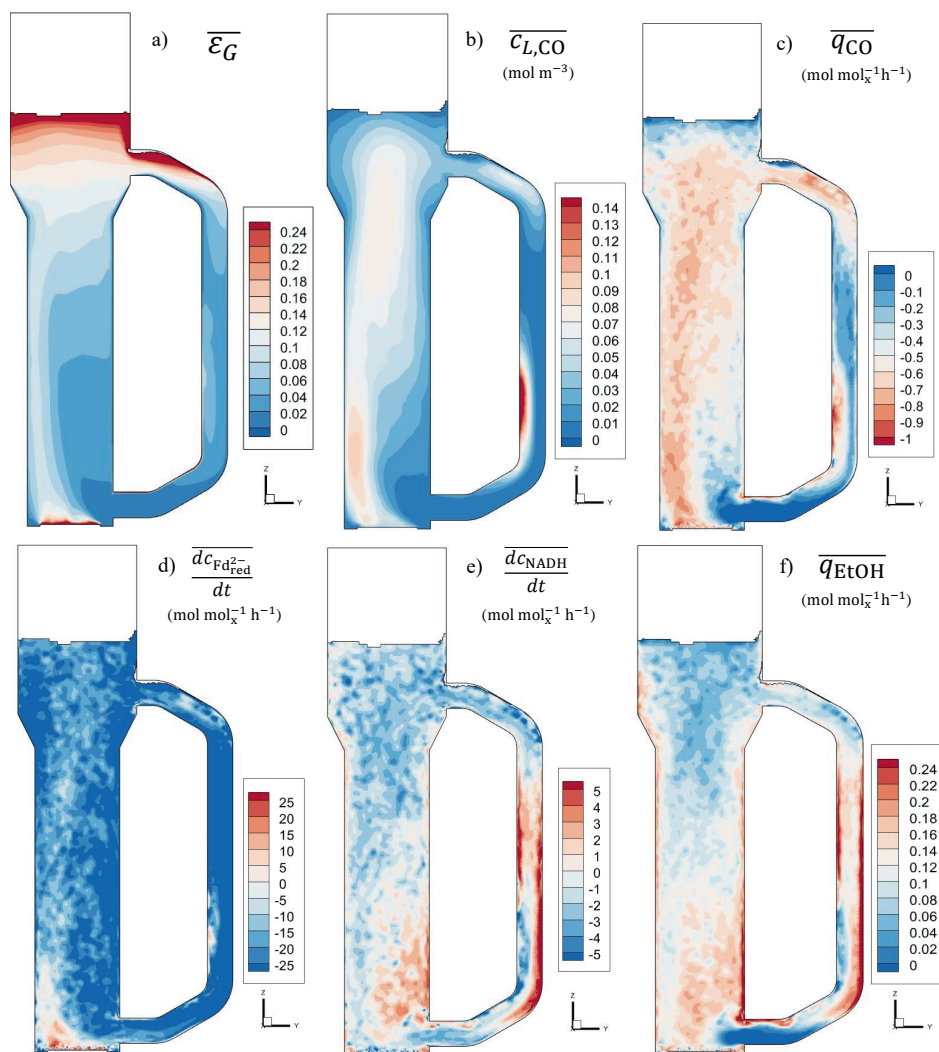

Figure 5.3: Spatial variations in gas hold-up and metabolites in the EL-GLR. Surface plots in the  $zy$ -plane ( $x=0$ ) of the EL-GLR with time-averaged a)  $\varepsilon_G$ , b)  $c_{L,CO}$ , c)  $q_{CO}$ , d,e) ferredoxin and NADH reduction rates (red) and oxidation rates (blue) respectively, f)  $q_{EtOH}$ . The results are time-averaged during the whole simulation duration of 1000 s, with  $c_x = 5 \text{ g L}^{-1}$ .

separator), high re-oxidation rates of ferredoxin are observed. As soon as  $\text{Fd}_{\text{red}}^{2-}$  is oxidised,  $\text{NAD}^+$  is reduced and ethanol is produced (Figure 5.3e,f). The model predicts an inverse relationship between the ferredoxin redox state and the ethanol production rate; in zones where ferredoxin is reduced, little ethanol is produced, while ethanol is produced in zones where ferredoxin is oxidised. As a consequence, ethanol is mainly produced in zones with low  $\varepsilon_G$  and  $c_{L,CO}$  (cf. Figure 5.3b, e). From a microbial point of view, faster variations in

dissolved gas concentration are expected to lead to faster ferredoxin oxidation/reduction cycles, and increased variations in  $q_{\text{EtOH}}$ .

Our model predicts via correlation analysis of lifeline data a significant delay (at least 15 s, with 5 and  $3.75 \text{ g}_x \text{ L}^{-1}$ , and even 30 s with  $2.5 \text{ g}_x \text{ L}^{-1}$ ) between CO consumption and ethanol production, governed by the dissolved gas concentration gradient: only when  $c_{\text{L,CO}}$  (and  $c_{\text{Fd}_{\text{red}}^{2-}}$ , section 5.3.5) decrease,  $q_{\text{EtOH}}$  increases. This lag time is slightly shorter ( $\sim 25\%$ ) than the circulation time, indicating that ethanol is being produced in a rather short period within the circulation. This is in sharp contrast with results from black-box and genome-scale metabolic models (using dFBA simulations), which both assume metabolic steady-state and show high production rates at locations with high gas uptake rates [75]. In our case the reactor can be subdivided in two zones: (1) a ferredoxin reduction zone and (2) a re-oxidation zone. Video S2 clearly shows the consequential differences in ethanol production zones compared to the black-box model. While further research is required to confirm these predictions, the model suggests a process design and operation that produces multiple, but smaller, of these zones, leading to shorter redox cycles, and improved ethanol productivity.

### 5.3.3. Analysis of characteristic times

Estimation of characteristic and turnover times is a widely used method for quick assessment of reactor performance and identification of limiting processes [48–50]. From the CFD-CRD model of the EL-GLR becomes clear that mixing and mass transfer are equally slow and generally slower (i.e., higher characteristic time) than CO-uptake (Figure 5.4), indicating that a dissolved CO gradient exist (in the cases with  $3.75$  and  $5 \text{ g}_x \text{ L}^{-1}$ ), which was confirmed in Figure 5.3b.  $\text{H}_2$ -uptake is significantly slower than CO-uptake, and its high characteristic time is expected to lead to a spatially well-distributed  $c_{\text{L,H}_2}$ . The slow  $\text{H}_2$ -uptake mechanism was expected from experiments [45], as  $\text{H}_2$  is thermodynamically the less preferred electron source in a gas mixture [242], and the cell can generate more ATP and reducing equivalents ( $\text{Fd}_{\text{red}}^{2-}$ , NADH, NADPH) per electron from CO than  $\text{H}_2$  [243]. The  $\text{H}_2$ -uptake rates predicted with the CFD-CRD model are significantly lower than the ones that were predicted with the Monod kinetics used in our previous study (Figure D.7), indicating differences between models on the kinetic behaviour of  $\text{H}_2$ -uptake.

The model predicts that electron storage is done mainly via the ferredoxin pool. The  $\text{Fd}_{\text{red}}^{2-}$  pool has a similar turnover time compared to CO-uptake, especially in the transport limited regime with  $5 \text{ g}_x \text{ L}^{-1}$ . The turnover times mainly depend on the concentrations of the metabolite pools, causing that NADH and NADPH show a 100 and 10 time lower turnover time, respectively, which indicate even faster redox cycles of  $\text{NAD}^+$  and  $\text{NADP}^+$ .  $\text{Fd}_{\text{red}}^{2-}$  can thus be hypothesised as an electron buffer for the cell. As the intracellular concentration of  $\text{Fd}_{\text{red}}^{2-}$  was never measured, this hypothesis remains to be verified, although low concentrations of NADH and NADPH have indeed been measured before [204].

**Figure 5.4:** Characteristic times for metabolite consumption, mass transfer and mixing. A spatial gradient may be present when the characteristic times are below the dashed grey zone, representing transport limitations. Turnover times of the metabolite pools were computed as the median of the ratio of the metabolite pool size and its depletion rate for 4000 lifelines ( $\tau_i = c_i/J_i$ ). Error bars represent the standard deviation over 4000 lifelines considering a normal distribution. Following the models in [224],  $k_L a$  was derived as the 900 s time- and volume-averaged  $k_L a$  of CO, with the error bar representing the standard deviation during that period, while the circulation time  $t_c$  was estimated via  $t_m$  (1/4 of the 95% mixing time of 90 s in every case [71]).

5

Similarly, the turnover time of acetate is high, while the other intermediates in the Wood-Ljungdahl pathway (formate and acetyl-CoA) are depleted significantly faster, in the cases with higher  $c_x$ . This shows a relatively fast pathway from acetyl-CoA to acetate production, despite the high concentrations of intracellular acetate due to the low pH (5.0) and the high extracellular concentration of acetic acid (90 mol m<sup>-3</sup>). An interesting observation is the high formate turnover time: In the case with 2.5 g L<sup>-1</sup>, formate is overproduced at highly reduced conditions (with very high  $c_{\text{Fd}^{2-}_{\text{red}}}$ , and correspondingly at high  $c_{\text{L,CO}}$ ) (Figure D.9). Formate production has been observed experimentally to relate with pressure [169, 244], or with very low biomass concentrations [41], both resulting into very high  $c_{\text{L,CO}}$ .

The fast turnover time of CO suggests that the two-way coupling is not needed for the prediction of the  $c_{\text{L,CO}}$  gradient, since a one-way coupling routine (with the Haldane kinetics) could also predict a similar gradient and lifelines. The CO- and H<sub>2</sub>-uptake rates in the CRD model are, however, predicted by considering the intracellular concentrations, which could lead to an inhibition effect (see section 5.3.5). In order to account for such effects, implementation of a two-way coupling strategy is required.

### 5.3.4. Influence of dissolved CO on product spectrum

To study the influence of the concentration gradient on the global reactor performance, the results from the CFD-CRD simulations, based on their time-averaged biomass-specific uptake, product formation rates, and observed concentrations, were compared with the results from the model with constant dissolved gas concentrations (Figure 5.5). To check

the correspondence of the model predictions with experimental trends and values, we retrieved  $q_i$  and calculated  $c_{L,CO}$  for several chemostat experiments. Overall, the trends and the values of the experimental studies corresponded well to those predicted by the model.

The models overestimate the average CO-uptake rate compared to experimental data at high  $c_{L,CO}$  (Figure 5.5a). This led to a rather constant  $q_{CO}$  while there was a large spread in  $c_{L,CO}$  in our model, rendering  $q_{CO}$  unsuitable for trend analysis. This is partly due to the calibration of the CRD model, which predicted  $q_{CO}$  consistently around  $1 \text{ mol mol}_x^{-1} \text{ h}^{-1}$  while more variation was observed in the experimental data [218]. The (Haldane and Monod-type) kinetic models that have been developed so far (e.g., [34, 40, 208]), are unable to predict the high  $q_{CO}$  that is observed experimentally (e.g., [45]). We noticed wide variability in  $q_{CO}$  in chemostat experiments with low  $c_{L,CO}$ . Due to this variability and the lack of models that adequately link  $c_{L,CO}$  and  $q_{CO}$ , we are unable, at this point, to establish any hypotheses or trends based on  $q_{CO}$ , and decided to focus our analysis on the role of  $c_{L,CO}$  on the product spectrum.

Acetate production (Figure 5.5b) is slightly underestimated by the model in all scenarios, but the trend clearly corresponds: more acetate is produced at higher  $c_{L,CO}$ . The trend of  $q_{EtOH}$  and the ethanol-per-electron yield (Figure 5.5c,d) match surprisingly well with the experimental data, and is clearly inverse to the acetate trend: more ethanol is produced at lower  $c_{L,CO}$ . This relationship is also visible in the acetate-per-ethanol ratio (Figure 5.5e), where it is clear that  $q_{EtOH} > q_{AcT}$  at  $c_{L,CO} < 0.1 \text{ mol m}^{-3}$ . Our model and experimental data suggest that ethanol is produced at the expense of acetate at lower  $c_{L,CO}$ , while acetate is produced at the expense of ethanol at high  $c_{L,CO}$ .

The CFD-CRD model suggests that the gradients expected at scale benefit ethanol production, since consistently a significant ( $\sim 25\%$ ) higher  $q_{EtOH}$  and  $q_{EtOH}/q_{e^-}$  and lower acetate production are predicted, compared to the results obtained without concentration fluctuations ( $p < 10^{-4}$  in all  $c_x$  cases using a one-sample  $t$ -test, wherein the distribution of lifelines is compared to the mean result of the constant concentration model in that respective range). Section 5.3.5 further explores potential reasons behind this behaviour. Another interesting observation is that at large-scale, population heterogeneity is likely to be observed, visible from the wide scattering of the lifeline-averages in Figure 5.5. The relatively short simulation duration of the CFD-CRD model could be a factor underlying the scattering, but given the currently available computational resources longer two-way coupled simulations with such a resolution are practically unfeasible. For example, to match the long simulation time of the *P. chrysogenum* industrial fermentation (70 hours) with the current model setup,  $\sim 14$  years of simulations would be required. The development of reduced order models (e.g., compartment models) could be a solution to alleviate this problem [226–228].

Our model, in conjunction with experimental data, indicates that  $c_{L,CO}$  is a key factor influencing the onset of solventogenesis. At high  $c_{L,CO}$ , acetogenesis prevails; however, as  $c_{L,CO}$  decreases below  $\sim 0.1 \text{ mol m}^{-3}$ , ethanol production rate surpasses that of acetate production. A phase guided by electron supply shortages and energy starvation has been observed at very low dissolved gas concentrations ( $c_{L,CO} < 0.05 \text{ mol m}^{-3}$ ). In this phase, there is a net consumption of acetate: Acetate is reduced to ethanol, with CO serving as an electron source essential for growth and maintenance (through ATP production via Rnf). As the re-oxidation of the electron carriers occurs via the AOR route, acetate – which freely diffused into the cell as acetic acid – is being converted into ethanol [233, 240]. This phenomenon was also observed in the second reactor in [31], with biomass recycle and high CO conversion and probably very low  $c_{L,CO}$ , where both acetate and CO consumption resulted into very high ethanol productivity, although this particular result could also be linked to shortages of essential nutrients as vitamins and metals. It is well known that acetate supplementation enhances the ethanol productivity [39, 41, 199], while it has been demonstrated that exogenously introduced  $^{13}\text{C}$ -labelled acetate was converted into  $^{13}\text{C}$ -labelled ethanol on CO-grown *C. autoethanogenum* [199]. All these observations lend support to the feasibility of this starvation-induced metabolism at low  $c_{L,CO}$ .

A simple thermodynamic analysis could explain why more ethanol is produced at lower  $c_{L,CO}$  (Table D.5). During ethanol production, more ATP is produced compared to acetate production ( $\sim 2$  vs.  $1.5 \text{ mol}_{\text{ATP}}/\text{mol}_{\text{product}}^{-1}$ ) [233, 245], since ethanol production releases more energy ( $\text{kJ mol}_{\text{CO}}^{-1}$ ) [32], and it is thus not a surprise that ethanol production relates to growth, confirmed both experimentally [45] and in our model (Figure D.12). When more CO is available, acetate might be produced since there is enough carbon and energy resource for growth, relating to the hypothesis of maximum energy dissipation [246]. The resulting acetic acid decreases pH (increasing the proton motive force used for energy generation), safeguarding sustainable growth in the future. From an evolutionary perspective, it might be that this presents a competitive advantage against other microorganisms [247], and thus a survival strategy in nature. Ethanol production via solventogenesis might then only be a (stress) reaction to preserve more energy at low dissolved gas concentrations, while in case with even lower  $c_{L,CO}$ , the starvation metabolism is employed for increased energy generation.

As large parts of the data used for the generation of Figure 5.5 were outside the calibrated range of the model (i.e.,  $c_{L,CO} < 0.025 \text{ mol m}^{-3}$ ), a similar figure was generated without considering that data in this range (Figure D.10). Obviously, this led to higher average  $c_{L,CO}$  and a lower spread in  $c_{L,CO}$  amongst lifelines. More interestingly is the decreased  $q_{\text{EtOH}}$  for the  $5 \text{ g L}^{-1}$  case (as noted in section 5.3.1), while the trends for all compounds remained similar among the complete  $c_{L,CO}$  domain. The gradient still led to significant ( $p < 10^{-4}$ ) increases in  $q_{\text{EtOH}}$ . The uncertainty in the very low  $c_{L,CO}$  range requires caution for quantitative analysis under these conditions.

Figure 5.5: Comparison of lifeline-averages from the CFD-CRD model with the constant concentration model and experimental data. The average biomass-specific rates and yields are plotted against the average  $q_{L,CO}$ : a)  $q_{CO}$ , b)  $q_{AcT}$ , c)  $q_{EtOH}$ , d) the electron-to-ethanol yield  $q_{e^-} = 1/2(q_{CO} + q_{H_2})$ , and e) the acetate-per-ethanol ratio  $q_{AcT}/q_{EtOH}$ . The scatters, with varying transparency to reduce overplotting, represent 900 s averages for ~4000 lifelines for each  $c_x$  simulation (blue 2.5; green 3.75; yellow 5 g L<sup>-1</sup>), the dashed line simulations with constant dissolved gas concentrations at the indicated biomass concentrations, and the markers reconciled [218] experimental chemostat data:  $\blacklozenge$  [44];  $\blacksquare$  [46] (CO + H<sub>2</sub>);  $\blacktriangle$  [90];  $\bullet$  [45].  $c_{L,CO}$  in  $\blacktriangleright$  [89], was estimated using their provided  $k_L a$

### 5.3.5. Metabolism during dynamic conditions

Figure 5.6: Metabolism of *C. autoethanogenum* during large-scale gas fermentation. 100 seconds of a lifeline for the case with  $3.75 \text{ g}_X \text{ L}^{-1}$  is shown with its concentration (in  $\text{mol m}^{-3}$ ) and rate (in  $\text{mol mol}_X^{-1} \text{ h}^{-1}$ ) fluctuations. Pool sizes and arrow thickness are approximative to the median concentrations and rates during the whole lifeline. The metabolism in the cases with  $2.5$  and  $5 \text{ g}_X \text{ L}^{-1}$  are provided in the supplementary material (Figure D.13 and D.14). Shaded areas in the plots mark zones with  $c_{L,CO} < 0.025 \text{ mol m}^{-3}$ .

The effect of the dissolved gas concentration fluctuations in the EL-GLR on the concentrations of metabolites and the modelled rates are schematically depicted in Figure 5.6. This representation allows us to follow the route of the carbon (blue lines) and electrons (green lines) and gives an impression on which processes drive the production of ethanol.

Following the carbon, a direct coupling between CO-uptake and acetate synthesis is seen. The Wood-Ljungdahl pathway, represented with the ACAS flux ( $J_{ACAS}$ ) in Figure 5.6,

is almost always activate with fairly constant rate, although it gets an impulse during a period at low  $c_{L,CO}$  due to the increased NADH availability in the cell. Consequently, the AcCoA concentration follows the peaks of dissolved CO, although it is slightly influenced by the periods at low CO. The net amount of AcCoA slowly decreased during the analysis, a trend also observed in the simulation with constant dissolved gas concentrations (Figure D.2). The rate of acetate formation ( $J_{ACS}$ ) follows the CO availability, albeit slightly lower than  $J_{ACAS}$ , since small amounts of AcCoA are also being used for the formation of biomass and 2,3-BDO. The cell is continuously busy with the acetate import/export cycle: High rates of  $J_{ACX}$  and  $J_{HACD}$  were predicted ( $\sim 0.45$  and  $\sim 0.40 \text{ mol mol}_x^{-1} \text{ h}^{-1}$ , respectively), around three times higher than its formation rate via  $J_{ACS}$ . Despite these efforts, there is still some acetate accumulation in the cell. In the case with less biomass, there is more acetate export, but also more intracellular acetate accumulation, while lower intracellular acetate concentrations are obtained in the case with more biomass. In the latter case, there is net consumption of acetic acid ( $J_{HACD} > J_{ACX}$ ), which leads to increased ethanol production rates; the starvation-induced metabolism, as explained in the previous section.

Most ( $\sim 75\%$ ) of the consumed CO is being used for electron capture with CODH, thereby producing  $\text{CO}_2$  ( $J_{CODH} > J_{FDH}$ ), and reducing ferredoxin.  $c_{\text{Fd}_{red}^{2-}}$  follows the same profile as  $c_{L,CO}$ , but its fluctuations are slower and less steep, showing its electron buffering capacity. Around 70% of the reduced ferredoxin is re-oxidized due to Rnf activity, the enzyme that shuttles the electrons from  $\text{Fd}_{red}^{2-}$  to  $\text{NAD}^+$  [248], and translocates protons across the cell membrane for the generation of the proton motive force and ATP [231]. NADH, in turn, is mostly used to drive the Wood-Ljungdahl pathway (ACAS) and for the production of the NADPH (via Nfn) that is required for ACAS and FDH.

In a period with low  $c_{\text{Fd}_{red}^{2-}}$ ,  $q_{\text{H}_2}$  is increased which relates to increased  $q_{\text{EtOH}}$  (Figure D.8, D.11). The first observation could relate to inhibition of  $q_{\text{H}_2}$  by reduced ferredoxin, while a similar (but weaker) trend was obtained for CO-uptake. This caused that decreased CO- and  $\text{H}_2$ -uptake rates were actually observed at high reduced ferredoxin concentrations, and not at high CO or  $\text{H}_2$  concentrations *per se* (cf. Figure D.7 and D.8). Inhibition of gas uptake could thus, next to binding of CO to hydrogenases, also be explained by a highly reduced intracellular state (i.e., too high intracellular concentrations of electron carriers), as was hypothesised before [249]. Our model results and chemostat experiments [45, 46] show that  $q_{\text{H}_2}$  proportionally relates to  $q_{\text{EtOH}}$ . The ferredoxin that is reduced due to  $\text{H}_2$ -uptake is probably instantaneously being re-oxidized again to drive EtS and Rnf (Figure 5.6). Because of the temporary lack of reducing equivalents, this mechanism guarantees electron inflow even at  $c_{L,CO}$ .

At dynamic conditions, a direct relationship between  $c_{\text{Fd}_{red}^{2-}}$  and  $c_{L,CO}$  ( $c_{\text{Fd}_{red}^{2-}}$  increases with  $c_{L,CO}$ ) is observed (Figure 5.7a), while  $c_{\text{Fd}_{red}^{2-}}$  shows an inverse hyperbolic relationship to  $q_{\text{EtOH}}$  (Figure 5.7b). This indicates that, irrespective of other phenomena occurring in the cell,  $q_{\text{EtOH}}$  is mostly determined by the temporal  $c_{\text{Fd}_{red}^{2-}}$ . If other phe-

**Figure 5.7:** Mechanism towards ethanol production in a lifeline. a) The relationship between the concentration of electron carriers  $\text{Fd}_{\text{red}}^{2-}$  (blue) and NADH (orange) is shown and their corresponding  $c_{L,\text{CO}}$  ( $c_{\text{Fd}_{\text{red}}^{2-},\text{max}} = 11.5 \text{ mol m}^{-3}$ ,  $c_{\text{NADH},\text{max}} = 0.04 \text{ mol m}^{-3}$ ). b) the relationships between acetate production (extracellular + intracellular) (black) and ethanol production (green) with  $c_{\text{Fd}_{\text{red}}^{2-}}$ . c) the rates of NADH production (Rnf, darkblue) and consumption (Nfn, light blue; ACAS, green; Ethanol Synthesis, gold; BDO Synthesis; yellow) as function of  $c_{\text{Fd}_{\text{red}}^{2-}}$ . The scatters mark temporal observations during a lifeline (between 100 and 1000 s), and their density denotes the probability of occurrence. c) is an energy balance that can be made since  $\tau_{\text{NADH}} \ll \tau_{\text{Fd}_{\text{red}}^{2-}}$ . Shaded areas mark zones with  $c_{L,\text{CO}} < 0.025 \text{ mol m}^{-3}$ .

nomena would have influenced  $q_{\text{EtOH}}$ , a larger spread in  $q_{\text{EtOH}}$  would be observed at the each  $c_{\text{Fd}_{\text{red}}^{2-}}$ . The NADH concentration shows a strong relationship with  $c_{\text{Fd}_{\text{red}}^{2-}}$  ( $c_{\text{NADH}}$  decreases with  $c_{\text{Fd}_{\text{red}}^{2-}}$ ), so on its turn  $c_{\text{NADH}}$  proportionally relates to  $q_{\text{EtOH}}$ , as was shown experimentally [233, 234, 250]. We could thus predict that, at some point, with low  $c_{L,\text{CO}}$  and thus low  $c_{\text{Fd}_{\text{red}}^{2-}}$ , high amounts of NADH and consequentially increased  $q_{\text{EtOH}}$  are obtained. The increased  $q_{\text{EtOH}}$  is due to decreases acetate production (Figure 5.7b), this way conserving mass balances (Figure D.5).

The delay that is observed between CO-uptake and ethanol production (a peak in  $q_{\text{EtOH}} \sim 50$  s; Figure 5.6) is present when  $c_{L,\text{CO}}$  and, and consequentially  $c_{\text{Fd}_{\text{red}}^{2-}}$ , decreased enough to stimulate ethanol production. For example, no clear increase in  $q_{\text{EtOH}}$  is observed after peaks in  $c_{L,\text{CO}}$ , until  $c_{\text{Fd}_{\text{red}}^{2-}}$  decreases to  $\sim 6 \text{ mol m}^{-3}$ , when also  $J_{\text{ACS}}$  slows down, reducing acetate production. Therefore, the delay is caused by the dynamics in the EL-GLR and causes that the microorganisms cycle between two states: one state with high  $c_{L,\text{CO}}$  and  $c_{\text{Fd}_{\text{red}}^{2-}}$ , and thus low  $c_{\text{NADH}}$  and  $q_{\text{EtOH}}$ , and another state with low  $c_{L,\text{CO}}$  and  $c_{\text{Fd}_{\text{red}}^{2-}}$ , but with increased  $c_{\text{NADH}}$  and  $q_{\text{EtOH}}$ .

Dissolved CO concentration fluctuations (e.g., with increased  $c_x$ , Figure D.14) induce the mentioned redox cycling and ethanol production. This happens at the expense of the intracellular acetate pool and  $J_{\text{ACS}}$ , and in the long term at the expense of the extracellular acetate concentration. The non-linear behaviour of metabolism (here described by lin-

log kinetics), the irregular duration and the large variation in  $c_{L,CO}$  in low concentration zones ( $< 0.05 \text{ mol m}^{-3}$ ) might cause that non-linear increases in ethanol productivity are observed upon concentration fluctuations. The effect of such variations has never been determined experimentally, a good start for experimental verification would be the developed scale-down simulator in our previous paper [224].

The only reaction that reduces  $\text{NAD}^+$  to NADH in the CRD model is Rnf, which is active in the whole  $c_{\text{Fd}_{\text{red}}^{2-}}$  domain (Figure 5.7c). The resulting NADH is mostly used in the Wood-Ljungdahl pathway (by ACAS), while a small fraction is used for NADPH generation, which is also required in ACAS. At lower  $c_{L,CO}$  and  $c_{\text{Fd}_{\text{red}}^{2-}}$ , Rnf activity increases while the majority of the resulting NADH is re-oxidized via the Ethanol Synthesis pathway. Thus, the increased Rnf activity at lower  $c_{\text{Fd}_{\text{red}}^{2-}}$ , can be associated to increases in  $q_{\text{EtOH}}$ . Metabolic models have previously predicted that increased Rnf activity relates with increased ethanol production in syngas fermenting *Clostridium spp.* [44, 45, 90, 243], although such relationships have never been observed experimentally. A proportional relationship between Rnf and ethanol production was found, however, in *C. thermocellum* grown on cellobiose [251].

The CFD-CRD model also predicts a coupling between ethanol production and growth rate. At higher growth rates, more ethanol is produced (Figure D.12) which complies with experimental observations (e.g., [45]). This might be because growth happens when there is more ATP available and that is the case when Rnf is more active as Rnf increases the proton motive force. No relation, however, between acetate production ( $q_{\text{AcT}}$ ) and growth rate was observed (Figure D.12), which might explain the contrasting experimental data regarding growth rate.

### 5.3.6. Emerging hypotheses

By mathematically modelling syngas fermentation, we derived a mechanistic understanding on how the dissolved gas concentration (and its fluctuations) influence the product spectrum of *C. autoethanogenum*, which we could support with experimental evidence. Thus far, experimentalists made statements that, for example, *i*) higher dilution rates increase  $q_{\text{EtOH}}$  [45, 240], *ii*) that lower mass transfer rates result in lower  $c_{L,CO}$  [41], or *iii*) that increased pressure leads to increased formate production [169]. But, by linking  $c_{L,CO}$  (and potentially  $q_{\text{CO}}$ ) to the product spectrum, we could merge such statements into one overarching explanation, by suggesting that *i*)  $q_{\text{EtOH}}$  is increased at lower  $c_{L,CO}$ , *ii*) that acetogenesis occurs at increased  $c_{L,CO}$  and that *iii*) formate accumulates in over-reduced situations (very high  $c_{L,CO}$  and  $c_{\text{Fd}_{\text{red}}^{2-}}$ ). In practice, this might mean that, for example, the faster growth in [45], coupled to high  $q_{\text{CO}}$ , might have led to the fall in  $c_{L,CO}$  so that  $q_{\text{EtOH}}$  is increased. The inverse relationship between  $q_{\text{CO}}$  and  $c_{L,CO}$  indicates a very low  $K_S$  (supported by thermodynamics [32]) and low inhibition constant  $K_I$  for Haldane kinetics, consistent with the experimentally expected fast  $\text{CO}$ -uptake [33, 45, 229]. Meanwhile, the increased acetate concentration should be noted in the discussion [39, 41]. To test our

observations, the influence of  $c_{L,CO}$  on  $q_{CO}$  and  $q_{EtOH}$  should be studied in chemostats with CO measurements (e.g., using the protocol in [252] or estimated following [218]) and with fixed operating conditions (i.e., constant growth rates and liquid phase concentrations). As a result, researchers on gas fermentation should link their results to microbial experiences, and thus dissolved gas concentration, and not to operational factors at the reactor-level such as pressure, dilution, or mass transfer rate (e.g., governed by stirrer speed).

The trends in Figure 5.7b might seem remarkable, from a steady-state point of view. For example, in chemostats it has been observed that increased electron (or dissolved gas) uptake rates increase  $q_{EtOH}$  [45, 240]. As electron uptake is associated to reduction of ferredoxin, which should lead to increased  $c_{NADH}$  and thus  $q_{EtOH}$ , it might seem controversial that, in our results, high  $q_{EtOH}$  is only obtained at low  $c_{Fd_{red}^{2-}}$ . We identified four hypotheses why we observed this trend in Figure 5.7b.

5

The first *i)* is that  $c_{Fd_{red}^{2-}}$  is around 100 times higher than  $c_{NADH}$ , causing that each  $NAD^+$  molecule needs to be reduced and re-oxidized 100 times in order to re-oxidize 100 ferredoxin molecules. This might cause that  $NAD^+$  is the limiting component in the Rnf reaction. This hypothesis might be tested by determining the  $c_{Fd_{red}^{2-}}/c_{NADH}$  ratio during over-reduced and under-reduced conditions, although it is experimentally very challenging and never done so far in gas fermenting bacteria.

Another hypothesis *ii)* might be related to the thermodynamics of the AOR pathway (acetate to ethanol reduction) as discussed in [234], where was stated that – at constant  $c_{Fd_{red}^{2-}}$ , due to long-lasting batch conditions – there is a linear relationship between the  $NADH/NAD^+$  ratio and the ethanol-to-acetate ratio (similar to our results, since  $q_{AcT}$  decreases when  $q_{EtOH}$  increases). If the  $Fd_{red}^{2-}/Fd_{red}$  ratio is increased in their model, at a constant ethanol-to-acetate ratio, a lower  $NADH/NAD^+$  ratio may be expected, similar to our model results in Figure 5.7.

Furthermore *iii)*, the time scale in a chemostat (order of days) is significantly longer than that of liquid circulation and mass transfer (usually > 20 s) and intracellular metabolite and uptake (< 1 s; Figure 5.4), which could lead to concentration gradients at lab-scale and similar  $c_{Fd_{red}^{2-}}/c_{NADH}$  fluctuations.

The last hypothesis *iv)* relates to binding of dissolved CO to iron-sulfur complexes present in Rnf [248, 253] or in ferredoxins [230], similarly to its binding to the Fe-S complexes in hydrogenases [11, 254, 255], and thereby inhibiting Rnf activity. When  $c_{L,CO}$  (and  $c_{Fd_{red}^{2-}}$ ) decreases, less Rnf inhibition might be obtained causing that its rate could be increased.

Clearly, too little is known at this moment on the metabolism of acetogens at low dissolved gas concentrations, and during dynamic conditions. To improve our understanding, experiments should be performed wherein *C. autoethanogenum* is exposed to short (5 – 30

s) shortages in  $c_{L,CO}$ , so that the effect of a metabolic stall can be studied, which can be used for model updates. Development of measurement methods for  $c_{Fd_{red}^{2-}}$  and  $c_{L,CO}$  at such conditions would be highly relevant. The ratio of reduced-to-oxidized ferredoxin was estimated to be high during batch fermentations, while the  $NADH/NAD^+$  ratio was more dynamic [234], although such results have not yet been obtained from chemostats or during conditions with dynamic gas supply, such as in the scale-down simulator described in [224].

We realise that the lin-log structure of the CRD-model bears several limitations. Results of lin-log models are good estimations around the reference conditions (i.e., around which they have been calibrated) [236], but in the CFD-CRD model, intra- and extracellular conditions far away from the reference concentration occur (see Table D.1). Despite the implemented rate-limitation modifications that were required for model stability, the CFD-CRD model still contained, although significantly dampened, numerical errors (Figure 5.2). We would therefore *not* recommend to use the lin-log structure for CRD models if they are to be coupled with CFD models, but instead stick to hyperbolic equations, analogous to [93, 94, 256] using mechanistic rate equations for intracellular reactions. Another limitation is the ultra-long simulation time of our CFD-CRD model, due to the large number of particles simulated ( $N_p = 80,000$ ), the short  $\Delta t_{IC}$  (0.1 ms) for integration, and poor parallelisation of the particle-based metabolic model. As a consequence, our simulations had a significant power consumption and environmental burden ( $\sim 0.45$  MWh and  $\sim 200$  kg  $CO_2$ ). The development and parameterisation time of the kinetic model took one year, and incorporation in the CFD model lasted around 6 months, so that development of CFD-CRD models should not be considered to be trivial. This demonstrates the balancing act between model purpose, complexity and resource availability (section 1.4).

Lastly, the CRD model could be improved by implementing several additional reactions. An export and back-diffusion cycle for formate should be added, together with the reaction for  $CO_2$  reduction to formate with  $H_2$ . Furthermore, there is some evidence that hydrogen can be produced from formate, using a  $NADP^+$ -based hydrogenase [249], which might be the cause of the simultaneous formate and hydrogen production in [41]. The parameters regarding the acetate export cycle are probably not well calibrated in the CRD model, since the model at low  $c_x$  predict large intracellular accumulation of acetate (Figure D.2). Implementation of an ATP balance or maintenance might also improve the model in this respect.

The clear spatial discrepancy between ethanol and acetate production zones might result in significant pH variations, in turn affecting the local  $q_{AcT}/q_{EtOH}$  ratio. Metabolic models that can predict variations in extracellular pH should be developed, and coupled with CFD to minimise the effect of non-ideal mixing and improve pH buffering.

### 5.3.7. Towards better gas fermentation bioreactors

The presented CFD-CRD model and its results could enable ways towards rational optimisation of gas fermentation, by adjusting operating conditions, the reactor geometry, and by strain engineering.

In terms of reactor operation, mass transfer limitations are desired: In case there are no mass transfer limitations, CO inhibition prevails, leading to low CO and H<sub>2</sub> conversion rates, while lower  $c_{L,CO}$  and higher conversion rates are obtained when there are mass transfer limitations [224]. In order to sustainably obtain high  $q_{EtOH}$  at industrial-scale, the average  $c_{L,CO}$  as experienced by the microorganisms should be kept in a narrow range, around the predicted optimum  $c_{L,CO}$  of 0.05 mol m<sup>-3</sup> according to our model (Figure 5.5e). A lower  $c_{L,CO}$  will induce too much acetate consumption, while at higher  $c_{L,CO}$  acetate will be produced at the expense of ethanol. When operating in a mass transfer-limited regime, high operational flexibility regarding  $c_{L,CO}$  can be obtained via the incoming gas flow rate, as this directly influences the gas hold-up and thus the mass transfer rate. For example, when there is too much acetate production ( $c_{L,CO}$  is too high), one could decrease the gas flow rate, which would decrease  $c_{L,CO}$ , so that produced acetate might be consumed again, leading to high ethanol productivities.

In terms of reactor geometry, clear zonation was obtained in the EL-GLR (Figure 5.3), with CO-uptake and ferredoxin reduction in one zone, and the ferredoxin re-oxidation and ethanol production in the other zone. As both processes can happen quite fast (order of seconds), and cellular transition between the zones was found advantageous for ethanol production, forced zonation can be an interesting way to increase ethanol productivity. To improve industrial-scale reactor design, future (lab and modelling) research could focus on determination of the ideal residence times in both zones, which can be implemented by altering the interior and exterior reactor geometry, and related operation conditions.

Lastly, increases in  $J_{Rnf}$  were found to be directly related to increases in  $q_{EtOH}$  (Figure 5.7c). Overexpression of Rnf (with deletion of hydrogenase) has been proven as a viable method to increase ethanol production in *C. thermocellum* [251]. Overexpressing Rnf may be a method to amplify  $J_{Rnf}$  at high  $c_{Fd_{red}^{2-}}/c_{NADH}$  and might increase  $q_{EtOH}$  even further in *C. autoethanogenum*.

## 5.4. Conclusion

In this work, we coupled a CFD model of an industrial-scale reactor for gas fermentation to a metabolic kinetic model to study the influence of the dissolved CO concentration and its gradient on the productivity and product spectrum of *C. autoethanogenum*. By comparing our model results with experimental data, we uncovered that the  $c_{L,CO}$  (and potentially  $q_{CO}$ ) is a major factor steering the product spectrum: Very low  $c_{L,CO}$  ( $< 0.05 \text{ mol m}^{-3}$ ) result in high ethanol production rates by reducing extracellular acetic acid, in a starvation-induced metabolism, slightly higher concentrations ( $0.05 < c_{L,CO} < 0.1 \text{ mol m}^{-3}$ ) were related to solventogenesis (CO to ethanol conversion), while high concentrations ( $c_{L,CO} > 0.1 \text{ mol m}^{-3}$ ) were associated with acetate production. The gradient at industrial-scale led to a  $\sim 25\%$  increase in ethanol production rate and yield, at the expense of acetate production. This increase was explained by redox cycles of ferredoxin and  $\text{NAD}^+$ , which are imposed when there is a gradient in  $c_{L,CO}$ . Due to the gradient, the concentration of reduced ferredoxin gradually decreases, while  $c_{\text{NADH}}$  increases due to Rnf activity. The re-oxidation of the resulting NADH caused led to enhanced ethanol production rates. We identified several hypotheses to support these results, made suggestions for follow-up research and developed a mechanistic understanding on the gas fermentation process.

# Chapter 6

## Conclusions

*A nice adaptation of conditions will make almost any hypothesis agree with the phenomena. This will please the imagination but not advance our knowledge.*

Joseph Black

**G**as fermentation has been described as a process dominated by multiple multi-scale phenomena. We characterised a commercial-scale bioreactor for gas fermentation (**Chapter 2**), to investigate the gas and liquid flow pattern and the global mass transfer rate (at the metre-scale). We hypothesised that the production of ethanol by the microbes would lead to significantly reduced bubble diameters, thereby facilitating high mass transfer rates. This led us zoom-in into the world of bubbles (**Chapter 3**) (millimetre-scale), and how they are influenced by the specific compounds, such as ethanol and the mineral medium ( $< 1$  nanometre), and the biomass concentration, in the fermentation broth. The impact of the biomass concentration, while considering small bubbles, on the dissolved gas concentration gradient was estimated in **Chapter 4**. This was used to develop a conceptual scale-down simulator, that could be used to mimic the concentration fluctuations from the large-scale in a lab-scale bioreactor (centimetre-scale). Such a system can be used to examine how these concentration fluctuations influence microbial metabolism. We developed several hypotheses for this by coupling a metabolic model of *C. autoethanogenum* (micrometre-scale) to the model of the large-scale reactor (**Chapter 5**). The dissolved gas concentration was identified as an influential factor regarding the product spectrum. The gradient resulted in increased ethanol production rates, which correlated with the activity of the Rnf-complex (at the nanometre-scale).

## 6

All these phenomena indicate that in a complex multi-scale process such as gas fermentation, the seamless integration of length scales and associated time scales is critical for bioprocess understanding and scale-up. Such a comprehensive approach is essential to assess the potential for bioprocess improvement from a broad physics- and biology-based mechanistic perspective.

Section 1.5 introduces several research questions which were aimed to be answered in this thesis. These answers will be briefly discussed below.

## Mass Transfer

- What are the factors that should be considered to achieve sufficient mass transfer rates for successful operation of a commercial-scale gas fermentation process?

A CFD model was developed, and validated on pilot-scale experimental data, to predict the gas and liquid flow pattern in industrial-scale external-loop gas-lift reactors (Chapter 2). Based on the predicted hydrodynamic conditions, it was found that very small bubbles ( $\leq 2$  mm) were required to obtain the reported industrial-scale  $k_L a$  ( $650 - 750 \text{ h}^{-1}$ ) and mass transfer capacity ( $7.5 - 8 \text{ g L}^{-1} \text{ h}^{-1}$ ). Such small bubbles may be due to the produced ethanol as it could suppress bubble coalescence and also increase (potentially  $>30\%$ ) the gas hold-up. The produced ethanol was therefore hypothesised to be the major contributor to high mass transfer performance at industrial-scale syngas fermentation.

This hypothesis was tested in Chapter 3 by adding  $50 \text{ g L}^{-1}$  of ethanol (the expected concentration at industrial-scale) to water, fermentation medium (without biomass) and

fermentation broths (including biomass), in a lab-scale bubble column. From determining the bubble size distribution, a structural decrease in bubble diameter (in  $d_{32}$ ) was obtained upon the addition of ethanol: from  $\sim 3$  mm in demineralized water and  $\sim 2$  mm in salt-containing medium and fermentation broths, to  $\sim 1$  mm with ethanol. In all cases, a more than 30% increase in gas hold-up was obtained after the addition of ethanol, although a decrease in mass transfer coefficient  $k_L$  was observed by adding ethanol or biomass. In these analyses, significant increases were obtained in  $k_L a$ : up to 6 times in pure water, and up to 4 times in fermentation broths and mineral medium. By measuring the properties of all the mixtures, it was concluded that the typical engineering correlations (based on air-water mixtures) that are used for bioreactor scale-up, are not suitable for fermentation broths with high salt, alcohol and biomass concentrations. Therefore, lab-scale experiments should be carried out to investigate the specific mass transfer properties of (expected) broths.

Pressure and temperature are operational variables that directly affect the solubility and  $k_L a$  of gaseous species (via  $\varepsilon_G$ ) (Figure 1.3). In Chapter 2 and 3, the influence of the operating temperature was examined. A substantial ( $\sim 40\%$ ) increase in  $k_L a$  was observed with a temperature increase from 20 to 37 °C, irrespective of the ethanol concentration, corresponding to commonly-used correlations. The effect of the headspace pressure on  $k_L a$  and mass transfer capacity ( $MTC$ ) was examined in Chapter 2. When the inlet gas mass flow  $\dot{m}_G$  is kept constant, a proportional decrease in  $u_{G,s}$  is observed, leading to a decreased  $\varepsilon_G$  and  $a$ , while a proportional increase in solubility is obtained. The result was that the headspace pressure had no significant effect on  $MTC$ . When  $\dot{m}_G$  is adjusted with pressure,  $MTC$  increases proportionally (but at higher operational costs).

In biotic operation at commercial-scale, mass transfer limitations were identified as desirable in gas fermentation. Mass transfer (with small bubbles) and microbial gas consumption were implemented in the CFD model of the large-scale reactor in Chapter 4. In cases with excess mass transfer a high dissolved CO concentration led to inhibition of CO and H<sub>2</sub>-uptake and low gas conversion. With mass transfer limitations, however, increased gas conversion rates were obtained due to the absence of CO inhibition. Gas consumption in these cases led to lower ( $\sim 33\%$ )  $\varepsilon_G$  and thus  $k_L a$ . This demonstrates the potential of the multi-scale coupling approach to investigate the effects of microbial gas consumption and mass transfer on the global reactor performance.

Across this thesis, the influence of several factors on mass transfer in gas fermentations has been investigated, such as pressure, temperature, reaction rate and, most importantly, the broth composition. The concentration of the produced ethanol has been pinpointed as a key factor for successful operation of commercial-scale gas fermentation.

## Downscaling gas fermentation

- What is an effective way to represent industrial-scale gas fermentation conditions at bench-scale?

After evaluating how high mass transfer rates could be obtained in the EL-GLR, the dissolved gas concentration and gradient were estimated for a wide range of conditions (Chapter 4). Based on lifeline analysis, microorganisms were likely to experience irregular fluctuations (between 5 and 30 s) in dissolved gas concentration (of around 1 order of magnitude), although with a wide spread in residence time in both peaks (moments with high concentration) and valleys.

To investigate how these concentration fluctuations affect the metabolism of acetogens, a conceptual scale-down simulator was designed. By imposing dissolved gas concentration fluctuations to a chemostat cultivation by irregularly modulating the stirring speed (with similar time distributions as in the large-scale reactor), similar concentration fluctuations can be experienced at both scales. By measuring metabolic properties like the gas consumption and product formation rates in both cases (chemostat with and without varied stirring speed), the influence of the gradient on variables such as  $q_{\text{EtOH}}$  could be determined.

The scale-down simulator was developed using the unstructured kinetic model for both CO and H<sub>2</sub>-uptake. The structured model (Chapter 5) predicted a lower H<sub>2</sub>-uptake rate than the unstructured model. This resulted in the absence of a dissolved H<sub>2</sub> gradient, although this was predicted with the other model. For successful development of a scale-down simulator regarding H<sub>2</sub>-uptake, more information on its kinetics should be obtained.

Lastly, it can be argued that the experiments done in Chapter 3 are scale-down studies with respect to mass transfer. With easy and standard methods, the influence of industrial-scale conditions (the ethanol concentration) on gas-liquid mass transfer was studied in a lab-scale bubble column. To do this more rigorously, a wider (> 0.15 cm [196]) and taller (> 1 m [26]) column should be used, while considering the relevant medium composition and biomass concentrations. Despite these features, this study gave good estimations how mass transfer could be enhanced at industrial-scale.

## Concentration gradient

- What is the influence of the dissolved gas concentration and its gradient on the metabolism and product spectrum of *C. autoethanogenum*?

The dissolved gas concentration and gradient were identified to be of major importance regarding the product spectrum (Chapter 5). By coupling the developed CFD model of an industrial-scale gas fermentor to a kinetic metabolic (CRD) model, for several biomass concentrations, lifelines with a wide range of relevant dissolved gas concentrations were obtained. The influence of the gradient was examined by comparing the CFD-CRD model

results with these obtained from solving the CRD model at constant dissolved gas concentrations.

Via this method was determined that the dissolved CO concentration was a key driver in the product spectrum. By comparing both model results with experimental chemostat data, clear trends with respect to  $c_{L,CO}$  were obtained. Acetogenesis was observed at high  $c_{L,CO}$  ( $> 0.1 \text{ mol m}^{-3}$ ), while solventogenesis is expected when ( $0.05 > c_{L,CO} > 0.1 \text{ mol m}^{-3}$ ). A starvation-induced metabolism wherein extracellular acetate is converted into ethanol was predicted at even lower  $c_{L,CO}$ .

The gradient was expected to significantly increase the ethanol production rate  $q_{EtOH}$  (with  $\sim 25\%$ ). The model predicted clear zonation in the reactor between the CO concentration and CO-uptake and  $q_{EtOH}$ . In zones with high  $c_{L,CO}$  ferredoxin could be reduced, which was found to act as buffer for electron storage. In the zones with low  $c_{L,CO}$ , the reduced ferredoxin is re-oxidised, releasing its electrons in NADH which is subsequently used for the conversion of acetate to ethanol. During the moments at low  $c_{L,CO}$  increased rates of the Rnf complex were likely (Rnf transports the electrons from reduced ferredoxin to NADH and translocates protons across the cell membrane, leading to the production of ATP). Several hypotheses were derived to explain this behaviour, and can be tested in further research, for example using the developed scale-down simulator.

# Chapter 7

## Moving forwards

*More research has to be done in this field.*

Every scientist

Last but not least, it is time to discuss the future of gas fermentation. We will do this by gradually zooming in from the role of gas fermentation in the bioeconomy, into the bioreactor and the concentration gradients, into bubbles and mass transfer and lastly into the bacteria. How could we make gas fermentation processes successful?

## 7.1. The landscape of gas fermentation

Gas fermentation recently gained a lot of industrial attention as many companies (from start-ups to the major chemical producers) are considering it in their process(es). The largest player in the gas fermentation field is LanzaTech, which is collaborating and licensing out their technology to dozens of companies, with various gas feedstocks: off-gases from the steel and ferroalloy industry, oil refineries and chemicals producers, but also gasified orchard wood and municipal solid wastes [103]. Meanwhile, LanzaTech diversifies its product portfolio, as they demonstrated acetone and isopropanol production with high productivity and selectivity at pilot-scale [9]. Many different products have been proposed, ranging from acids (lactic acid and 3-hydroxypropionate), ketones (acetone), alcohols (butanol, 1,3-butanediol, octanol) to dienes (isoprene), using genetic modification of *C. autoethanogenum* or synthetic co-cultures [7, 8, 11].

A preliminary thermodynamic assessment shows that the energy release by anaerobic gas fermentation is very modest, compared to other bioprocesses (Table 7.1). Although Cueto-Rojas et al. [83] mentions CO as a carbon source with high potential for anaerobic processes given its high Gibbs free energy content per electron ( $-47 \text{ kJ mol}_e^{-1}$ ), the low  $\Delta_R G^\circ$  (Table 7.1) requires high catabolic turnover rates for growth. Together with the inherent mass transfer limitations of CO, any non-catabolic process will be a very slow process, leading to poor growth rates and productivities. This causes that genetically modifying *C. autoethanogenum* to introduce a product reaction [11] might not be the way forward for gas utilisation.

Due to the limitations described here (i.e., low free energy release, mass transfer limitations), only short-chain catabolic products may be of relevance in anaerobic gas fermentation processes. Microbiologists should embrace these limitations, produce ethanol or acetate at high selectivity and find good uses for the product. Ethanol and acetate could both be used for production of single-cell protein via high-yield aerobic fermentation [29, 220, 257], or into medium-chain fatty acids [221], while ethanol can chemically be upgraded to (aviation) fuel or plastic. Therefore, anaerobic gas fermentation should be regarded more as a process to utilise waste gases with high global warming potential, and not so much as product-formation platform.

H<sub>2</sub> supplementation to CO gas mixtures improves the sustainability of ethanol formation, since less CO<sub>2</sub> will be produced (Table 7.1). This process is complicated from a bioprocess engineering perspective, since it is more challenging to steer  $q_{\text{CO}}$  and  $q_{\text{H}_2}$  in the right ratio than to feed with the specific gas composition (see Section 7.2). CO/H<sub>2</sub> fermentation faces severe competition with catalytic processes (like Fischer-Tropsch), such

that its application will be highly dependent on the gas composition (and impurities), and economic and environmental indicators.

If we take the risk to add oxygen to the gas mixture, everything changes drastically, as way more energy becomes available upon oxidation of CO and H<sub>2</sub> (Table 7.1). This is in favour of *knallgas* (CO<sub>2</sub>, H<sub>2</sub>, O<sub>2</sub>) fermentation (for which growth rates up to 0.42 h<sup>-1</sup> have been achieved, where  $k_{L,O_2}a$  was almost 3000 h<sup>-1</sup> (!) [258]). The energy release per mol carbon in this reaction is highly competitive with that of aerobic respiration processes. This explains the high number of start-ups that are currently researching this technology (amongst others, Deep Branch, Solar Foods) for production of protein or PHA [103, 259]. High mass transfer reactor designs ( $k_L a > 1000 \text{ h}^{-1}$ ) are required to make up for the very low O<sub>2</sub> content (< 6.9%) that is required to prevent flammable and/or explosive *knallgas* compositions.

**Table 7.1:** Thermodynamics of several gas-based bioprocesses [30], with some companies commercialising these processes [29, 103]. Anaerobic gas fermentation is compared with aerobic fermentation of gases and liquid substrates in terms of the Gibbs free energy at standard conditions, per mol reactant and per mol carbon [84].

Substrate	Reaction	$\Delta_R G^o$ (kJ mol <sup>-1</sup> )	$\Delta_R G^o$ (kJ mol <sub>C</sub> <sup>-1</sup> )	
<b>Anaerobic gas fermentations</b>				
CO	4 CO + 2 H <sub>2</sub> O → C <sub>2</sub> H <sub>3</sub> O <sub>2</sub> <sup>-</sup> + H <sup>+</sup> + 2 CO <sub>2</sub>	-135.0	-33.8

Anaerobic *gas* fermentation has its name for a reason, and should be treated as such, with preventing greenhouse gas emissions as main application. With the introduction of externality costs (charging for the environmental costs of greenhouse gases via taxes

or trading schemes) anaerobic gas fermentation processes become economically more attractive. Interesting gas sources might be industrial off-gases (steel mills, refineries), gasified municipal solid waste streams and (torrified) lignocellulosic biomass wastes. In all scenarios, greenhouse gas emissions are prevented (or the carbon lifeline extended).

The large ethanol market makes it possible to anaerobically convert these gases into useful products for society. Higher-value products might be produced by other fermentation processes, such as glucose or ethanol oxidation, with the knallgas reaction, or with catalytic processes. Gas mixtures derived from air-captured CO<sub>2</sub> and electrolytic hydrogen will possibly be expensive, requiring conversion to facilitate high-value (circular) processes, into e.g., sustainable aviation fuels.

## 7.2. Bioreactor operation for gas fermentation

### Bioreactor design

As the main goal of anaerobic gas fermentation is gas conversion (preventing greenhouse gas emissions), bioreactors should be designed as such. High biomass concentrations and mass transfer limitations will be the desired operational mode, since it prevents inhibition, improves the gas-to-product yield and enables control possibilities. This should be done by implementing methods that control the liquid flow rate and thus the gas hold-up, for example with an axial pump in the downcomer.

Enhancing mass transfer rates (provided its limitations remain by increasing  $c_x$ ) can be done by increasing both headspace pressure and gas flow rate (at economic costs), by decreasing the inert gas fraction, enlarging the gas inflow, or creating smaller bubbles by changing the medium composition (increase ethanol and salt content [24], risking a lower  $k_L$  by creating rigid bubbles).

Implementation of perforated plates might have a profound impact on gas hold-up and bubble size, and thus mass transfer. From simulations of an EL-GLR with perforated plate (15 cm thickness, 20% open area) using a porous medium model ( $C_2 \sim 3100 \text{ m}^{-1}$ ) significantly reduced CO mass flows were expected after passing the plate, compared to a model without plate (Figure 7.1). Overall, the plate increased CO conversion by around 15%, although the 95% mixing time increased from 90 s to 300 s. Future (lab and computational) research should focus on validation of the porous medium model for CFD modelling of perforated plates, and its application in bubble columns since it is a promising method to increase gas conversion.

The downcomer provides several operational advantages (e.g., enabling broth outflow, medium inflow, cooling). It also enlarges riser gas and liquid velocities, which decrease  $\varepsilon_G$  and  $k_L a$  relative to a bubble column operational mode, while friction in the downcomer increases mixing times [108]. An interesting subject for further study might be the influence of the downcomer on axial gas mixing. If the downcomer decreases axial gas mixing, then the gas behaves more like a plug flow in the riser, so that high gas fractions of CO and H<sub>2</sub> are obtained at locations with high hydrostatic pressure, while a well-mixed

Figure 7.1: Influence of a perforated plate on the CO mass flow in EL-GLRs. a) CFD-simulation without perforated plates, b) simulation with a perforated plate. See Chapter 4 for the configuration of the CFD simulations ( $c_x = 10 \text{ g L}^{-1}$ ).

gas phase will lead to decreased  $y_{CO}$  and  $y_{H_2}$ , which in turn might decrease  $MTC$ . Biotic and abiotic lab studies with gases (other than air) might be interesting for finding out when (depending on gas composition and gas flow rates) an external downcomer leads to increased mass transfer.

## Gas composition

As discussed in the previous section,  $H_2$  supplementation increases the biomass-specific ethanol production rate  $q_{EtOH}$ , and is an attractive method to increase the sustainability of the process. Operationally, it is not straightforward to match  $q_{CO}$  and  $q_{H_2}$  in the right ratios, due to varying mass transfer coefficients, Henry coefficients and the strong effect of CO inhibition on  $q_{H_2}$ . With the ideal-mixing model of the EL-GLR (Chapter 4) a quick assessment was done to estimate the optimal gas composition for ethanol production and to minimise  $CO_2$  production.

From this assessment it turns out that the best gas composition for ethanol production is rich in  $H_2$  (> 90%) and only has small traces (~5%) of CO and  $CO_2$  (Figure 7.2). If more  $CO_2$  is added to the gas, it accumulates in the liquid-phase due to its high solubility and is simply not converted. To obtain net zero  $CO_2$  production a gas mixture with 40% CO and 60%  $H_2$  should be used, different from the ratio in Table 7.1 (33.3% and 66.7%). The

**Figure 7.2:** Influence of the gas composition  $y_i$  on  $q_{EtOH}$  and  $q_{CO_2}$ . For a wide range of gas compositions the biomass-specific production rates for a) ethanol and b)  $CO_2$  (negative for consumption) were estimated using the ideal-mixing model of a large-scale reactor for gas fermentation (Chapter 4) with mass transfer limitations ( $k_{L,CO}a = 180 \text{ h}^{-1}$ ,  $c_x = 25 \text{ g L}^{-1}$ ),  $q_{CO_2} = \frac{4}{6} q_{CO} - \frac{1}{3} q_{H_2}$ . No inert gas fraction was assumed.

results are clearly influenced by the high  $q_{H_2}^{\max}$  since the  $q_{EtOH}$  can be almost 50% higher in a  $H_2$ -rich gas compared to  $CO$ -rich gas.

An interesting path for future research would be to perform such analyses with more detailed models for ethanol and  $CO_2$  production, such as the metabolic model in [40] and considering the dynamic conditions in large-scale reactors, since the concentration gradient has a substantial influence on the product spectrum (Chapter 5).

## 7

### Ethanol concentration

Product inhibition is a frequently observed phenomenon in fermentation processes (see Straathof et al. [63]). Alcohols were found to be a substantial inhibitor to growth of *Bacillus subtilis*, as function of carbon chain length [260]. If this effect would also hold for *C. autoethanogenum* then the ethanol concentration would be an important variable in process design as it directly affects the costs of downstream processing (via heating duty in distillation columns) [16]. Thus, high  $c_{EtOH}$  decrease downstream processing costs, would increase mass transfer rates due to coalescence inhibition (Chapter 3), while increased reactor volumes are required due to the decreased productivity and  $q_{CO}$ .

Ethanol inhibition was studied before in gas-fermenting *Clostridium* spp., although the mechanism is still unclear. A linear relationship between growth and  $c_{EtOH}$  (up to  $35 \text{ g L}^{-1}$ ) was obtained for *C. carboxidivorans* grown on  $CO$  [35], while [261] did not find any inhibitory effects up to  $15 \text{ g L}^{-1}$  for syngas-grown *C. ljungdahlii*. Based on long-term culture data with high  $c_{EtOH}$  up to  $50 \text{ g L}^{-1}$  with *C. ljungdahlii* [262], de Medeiros et al. [208] fitted a hyperbolic model for ethanol inhibition.

For successful process design, and determination of kinetic parameters for gas uptake, ethanol inhibition has to be studied more rigorously. Crucial parameters that need to

be determined are the critical inhibition concentration, the range of concentrations at which inhibition does not play a role regarding growth, and how ethanol inhibition can be mathematically described (linear, hyperbolic or exponential). This could be studied in chemostats with *C. autoethanogenum* with step changes in  $c_{\text{EtOH}}$  in the feed. Directed evolution studies might be a possible way to alleviate the effect of high  $c_{\text{EtOH}}$  in the long term. With clearance on the ethanol inhibition mechanism, integrated bioprocess design studies can be done to find out the optimal conditions for both the upstream and downstream processes.

### 7.3. Concentration gradients and scale-down

CO and H<sub>2</sub> concentration gradients were expected in the EL-GLR of roughly one order of magnitude (e.g., 0.02 – 0.2 mol m<sup>-3</sup>, depending on  $c_x$ ) with irregular peak and valley duration in the order of seconds (5 – 30 s). With the proposed scale-down simulator in Chapter 4, the impact of such concentration gradients can be studied at lab-scale.

Future work should employ the proposed scale-down CSTR bioreactor with variable stirrer speed to investigate whether the concentration gradient is of any advantage to ethanol production (see Chapter 5). With the data obtained from the scale-down setup, metabolic models could be parameterised (preferably based on hyperbolic enzyme kinetics), which can in turn be used to improve the CFD-CRD model and our understanding on gas fermentation dynamics. Such work could also shed light on the ideal duration in high and low concentration zones, which could in turn be used for improved bioreactor design, at both pilot and full-scale.

At lab-scale, despite the typical ideal mixing assumption, dissolved gas concentration gradients might also be obtained. This is most probably due to the specific flow pattern in the reactor, fast reaction kinetics and the very low gas flow rates (usually varying between 0.01 vvm in [41] and 0.1 vvm in [45]) gas fermentations. Even at pilot [9] and full-scale (Chapter 2) low gas flow rates <0.1 vvm were expected.

Based on short-cut CFD simulations of a typical lab-scale bioreactor [45], a  $c_{L,\text{CO}}$  gradient was expected between 0.02 – 0.05 mol m<sup>-3</sup> within a 0.75 L bioreactor (12 cm liquid height) (Figure 7.3a). Although this gradient is less significant than the one at larger scales, this was not expected with the ideal-mixing approximation. It was hypothesised that this non-ideal mixing may have a positive impact on  $q_{\text{EtOH}}$ .

The gradient arises probably due to depletion of CO from gas bubbles, and the fast reaction rate compared to mass transfer and mixing. In Figure 7.3b is visible that closer to the sparger the bubbles contain more CO than the ones near the walls and headspace. The consumed CO is partly replaced by the produced CO<sub>2</sub>. To decrease the CO gradient, axial mixing should be improved, for example by changing to an axial impeller.

By compiling data from several lab-studies,  $q_{\text{EtOH}}$  was found to be increased when reaction is faster than mixing (Figure 7.3c). As was hypothesised that  $q_{\text{EtOH}}$  may be increased to the  $c_{L,\text{CO}}$  gradient (Chapter 5), the conclusions obtained from these studies may be influenced by the gradient. Future research should focus on the existence of concentration gradients at lab-scale gas fermentations, and efforts should be made to diminish their impact when it is not the main topic of research.

One interesting method to obtain constant concentrations, is using microfluidic bioreactors [263, 264]. In microfluidic chips, the dissolved CO concentration can be controlled via regulated mixing with a fully saturated flow (e.g., [265]) or via a fully controlled gas chamber (e.g., [266]). In the microfluidic chip, acetogens can be cultivated at constant or dynamic conditions (following a lifeline [267]), and used to study the influence of  $c_{L,\text{CO}}$  on gas uptake kinetics, the product spectrum, and their reaction to concentration gradients. In the future (when cheap microfluidic chip fabrication is available), microfluidic cultivation is potentially an effective tool for strain selection and screening in scale-down studies.

## 7.4. Gas-to-liquid mass transfer

In this work was highlighted that the medium composition had a significant impact on mass transfer. In a follow-up review paper by Volger et al. [24], the influence of a wide range of broth constituents (e.g., salts, proteins, biomass, products, antifoam) on bubble column hydrodynamics and mass transfer was assessed. This made clear that the combined effects of broth components is barely understood, as the scientific literature is more focused on individual compounds. This all could lead to unexpected deviations in

Figure 7.3: Gradients in lab-scale gas fermentations. a) Time-averaged  $c_{L,\text{CO}}$  obtained using a short-cut Lattice-Boltzmann CFD simulation (in M-Star) of a 0.75 L reactor with operating conditions based on [45] (1160 rpm, 72 mL min<sup>-1</sup>, 1 mm bubbles,  $k_L$  via Equation 2.5 and reaction as modelled in Chapter 4). b) Bubble dispersion in that reactor, the bubbles are coloured with their  $y_{\text{CO}}$ . c) Compilation of experimental data depicting the relationship between  $q_{\text{EtOH}}$  and the ratio between reaction and mass transfer time (values below 1 indicate faster consumption than transfer).

variables important for mass transfer, with respect to the typical engineering correlations.

Industrialists and academics working on gas fermentation should study  $k_L a$  of their reactor with water and broth. This is required for successful scale-up, and can be used to calculate dissolved gas concentrations which can not yet be measured. Comparison of broth  $k_L a$  with water  $k_L a$  should provide proper estimations, as is common practice in wastewater treatment [185]. This can, for example, be done using the relatively simple and cheap methods used in Chapter 3.

The large amount of  $k_L a$  data in literature, could make it possible to develop databases with broth compositions, for example via AI-based literature-scraping tools [268]. Pattern recognition may indicate how specific components interact and influence broth  $k_L a$ .

In gas fermentation experiments, significantly higher  $k_L a$  were predicted from the gas consumption rate (Equation 7.1) than the one expected from the gas inflow rate and the amount of bubbles (Equation 7.2) (Figure 7.4a). For example, in a lab-scale reactor operated with 0.1 vvm [45] around 2000 bubbles were expected from simulations (Figure 7.3b) and Equation 7.2, resulting in a  $(k_{L,CO} a)_{abiotic}$  around  $3 \text{ h}^{-1}$  ( $d_b = 1 \text{ mm}$ ,  $k_L = 1 \times 10^{-4} \text{ ms}^{-1}$ , bubble residence time  $\tau_b = 1 \text{ s}$ ). This is significantly lower than the minimum biotic  $k_L a$  in [45] of  $180 \text{ h}^{-1}$ . Only with very extreme assumptions such high  $(k_{L,CO} a)_{abiotic}$  could be obtained ( $d_b = 0.1 \text{ mm}$ ,  $k_L = 3 \times 10^{-4} \text{ ms}^{-1}$ ,  $\tau_b = 3 \text{ s}$ ). Therefore, it would be interesting to determine how such high mass transfer rates are obtained at lab-scale, despite the small gas flow rates.

$$(k_{L,CO} a)_{biotic} = \frac{r_{CO}}{c_{L,CO}^{sat} - c_{L,CO}} = \frac{q_{CO} c_x}{c_{L,CO}^{sat} - c_{L,CO}} > \frac{q_{CO} c_x}{c_{L,CO}^{sat} - 0} \gg \frac{q_{CO} c_x}{H_{CO} p y_{CO,in} - 0} \quad (7.1)$$

$$(k_{L,CO} a)_{abiotic} = k_{L,CO} \cdot a_b \cdot N_b = k_{L,CO} \cdot \frac{4\pi d_b^2}{V_L} \cdot \frac{F_{G,in}}{\frac{1}{6}\pi d_b^3} \tau_b = 6k_{L,CO} \frac{F_{G,in}}{V_L d_b} \tau_b \quad (7.2)$$

One possibility might be that the mass transfer coefficient  $k_L$  is significantly enhanced, hinting at bubble boundary layer effects, as was extensively described in [269]. Such enhancement could be due to the presence of a cell layer around the bubble and by gas consumption in the boundary film layer. Very strong boundary layer effects (high Hatta number) would reduce CO availability in the bulk liquid and thus underpredict  $q_{CO}$ . This might explain the fourfold increase in  $q_{CO}^{max}$  as predicted based on recent experiments [270] relative to the one used in kinetic models (Table 4.1).

One method to measure biotic mass transfer enhancement during continuous gas fermentation might be by mass transfer of inert gases. For example, dynamic measurement of dissolved nitrogen<sup>1</sup> concentration after step changes in  $y_{N_2}$  [195] might reveal the abiotic  $k_{L,N_2} a$ , which can be converted into an abiotic  $k_{L,CO} a$  via their diffusion coefficients (Equation 4.13). This can then be compared with the biotic  $k_{L,CO} a$  as calculated using Equation 7.1.

<sup>1</sup>possibly via Hach Orbisphere 315xx Nitrogen Sensors.

**Figure 7.4:** Mass transfer uncertainties at lab-scale. a) Comparison of the minimum biotic  $k_L a$  (Equation 7.1) and estimations of abiotic  $k_L a$  (Equation 7.2) for various experimental conditions. b) Gas depletion from a bubble over time, calculated for various  $k_L$  values. Abiotic  $k_L a$  was estimated by assuming  $d_b = 1 \text{ mm}$ ,  $k_L = 1 \times 10^{-4} \text{ ms}^{-1}$ ,  $\tau_b = 1 \text{ s}$ . Results in b) were obtained using a diffusion-reaction model around a 1 mm gas bubble with initial  $y_{\text{CO}}$  of 0.5, a boundary layer thickness of  $2.71 \times 10^{-5} \text{ m}$ , and strong turbulent diffusion in the liquid ( $D_{\text{turb}} = 1 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$ ), kinetics as in Chapter 4,  $c_x$  of  $1.56 \text{ gL}^{-1}$  [45].

Gas bubbles are depleted faster due to mass transfer enhancement. With a diffusion-reaction model was predicted that a twofold increased  $k_L$  would reduce  $y_{\text{CO}}$  by 50% within 1 s (Figure 7.4b). A tenfold higher  $k_L$  would even lead to 95% CO depletion within that second. The 20-times increases in consumption rate (as predicted above), were not expected with this model. The large discrepancies between  $y_{\text{CO},\text{in}}$  and  $y_{\text{CO},\text{out}}$  (for example in [41]) challenge the estimation of CO solubility and thus  $k_L a$  and  $c_{L,\text{CO}}$ , so that the value obtained with Equation 7.1 is at the lower side.

All in all, the high gas conversion rates in lab-scale gas fermentations with low gas flows raise several questions that remain unanswered. Development of online dissolved CO sensors is paramount for further research on this topic. A good first step is the approach used by Mann et al. [252].

## 7.5. Gas fermenting bacteria

As mentioned throughout this work, there is a clear knowledge gap regarding gas uptake kinetics of acetogens. Although there are several experimental [33, 34] and modelling [40, 208] works that propose gas uptake kinetics, there are big discrepancies between the derived kinetic models and experimental results. The reason for this may be that many conditions influence gas uptake rates (e.g., the concentrations of dissolved CO, H<sub>2</sub>, acetate and intracellular reduced ferredoxin).

Future experiments to determine gas uptake kinetics should apply the dissolved CO measuring technique from [252], while keeping product concentrations constant (possibly by supplying them in the inflow). A good approach to determine  $q^{\text{max}}$  is the one

used in [270] (with smaller gas headspace volumes to shorten the cycles), while steady chemostat experiment with varying  $y_{i,\text{in}}$  could be done to study  $K_S$  and  $K_I$ . Dissolved gas gradients should be prevented by increasing axial mixing in the reactor and by working with high volumetric gas flow rates.

As  $\text{H}_2$ -uptake is inhibited by CO, the measurement of  $\text{H}_2$ -uptake kinetics becomes even more challenging. One interesting study could be to perturb  $\text{CO}_2$  and  $\text{H}_2$ -grown chemostat cultures with increasing amounts of CO and measure the variations in  $\text{H}_2$ -uptake rates from the off-gas.

In Chapter 5 several hypotheses were provided on the relationship between  $c_{\text{Fd}_{\text{red}}^{2-}}$  and  $q_{\text{EtOH}}$ . At this moment no methods are available for measurement of  $c_{\text{Fd}_{\text{red}}^{2-}}$  [271], so that a direct proof cannot be obtained.

Interesting studies can be done, however, on the Rnf complex, which rate was found to be related to ethanol production. For example, in chemostat cultures with varying  $c_{L,\text{CO}}$  (using the approach of [252]), next to obviously  $q_{\text{CO}}$  and  $q_{\text{EtOH}}$ , the concentrations of NADH and  $\text{NAD}^+$  should be determined (e.g., [234]) as well as the Rnf activity (e.g., [249]). This may identify whether the Rnf rate does indeed relate to  $q_{\text{EtOH}}$  as was hypothesised in Chapter 5.

Studies with cell extracts, similar to [249], could shed light on the inhibiting effect of CO on Rnf, for example by varying  $y_{\text{CO}}$  in the headspace or by saturation of demineralized water with CO. Such studies might also reveal whether Rnf is more sensitive to variations in  $\text{Fd}_{\text{red}}^{2-}/\text{Fd}_{\text{ox}}$  compared to  $\text{NADH}/\text{NAD}^+$ , as the latter one was expected to change more frequently during concentration fluctuations.

## 7.6. The end in mind

In this outlook chapter, we discussed the future of research on gas fermentation. The topic is very dynamic, and although commercial-scale processes are established, there are still too many unknowns compared to the more traditional fermentation processes. For successful scale-up of this technology, the main research gap are the kinetics of acetogens and their reaction to dynamically varying components (dissolved gases and products). With increased understanding on the effect of the broth and the biotic enhancement effect on mass transfer, the accuracy of CFD simulations can be improved.

With detailed kinetics and metabolic models, and increased understanding on gas-to-liquid mass transfer, gas fermentation bioprocesses and operating conditions can be optimised according to specific gas composition and desired end-products. Advances in AI and computer hardware (and availability) will drastically speed-up CFD-CRD simulations. Hydrodynamic-metabolic simulations might be run as a digital twin (fed with off-gas data) to enable real-life control.

Gas fermentation with air-captured CO<sub>2</sub> and electrolytic H<sub>2</sub> could lead to carbon-neutral production of commodities (fuels and chemicals) and even carbon-negative production of materials (plastics). Fast development of gas fermentation processes is crucial to combat climate change.

The future of gas fermentation is bright. Let's make it happen!

## Supplement Chapter 2

LanzaTech CO mass transfer capacity		Industrial $k_L a$	
Assumptions		Assumptions	
Production	48 kton/yr 6 reactors	Liquid height	25 m
Liquid volume	500 m <sup>3</sup> /reactor	CO gas fraction	0.5 mol CO/mol gas
Operating hours	8000 h/yr	Conversion	90 %
Stoichiometry	0.167 mol EtOH/mol CO	Henry coeff.	8.19 $\mu\text{mol}/\text{m}^2/\text{Pa}$
Formation of other products (X, Ac):	Köpke & Simpson (2020)	Pressure	101325 Pa
Specificity	0.95	Density	993.37 kg/m <sup>3</sup>
No accumulation of CO (steady-state)		Gravity	9.81 m/s <sup>2</sup>
		Dissolved CO conc.	0 kg/m <sup>3</sup>
		Assume ideal mixing	
Production	6000 kg etoh/hr/reactors	Calculation	
Transfer rate	130 kmol etoh/hr/reactors	Av. Pressure	223137 Pa
	824 kmol CO/hr/reactors	Average $Y_{CO}$	0.225 mol CO/mol gas
	23 ton CO/hr/reactors	Av. CO solubility	0.411 mol/m <sup>3</sup>
MTC	7.69 g CO / L broth / h		0.012 g/L
		$k_L a$	668 h <sup>-1</sup>
		Sensitivity analysis	
50 kton/yr	7.61 g/L/h	MTR	8.5 g/L/h
45 kton/yr	6.85 g/L/h	MTR	7 g/L/h
Specificity 1	7.3 g/L/h	20 m liquid height	750 h <sup>-1</sup>
Specificity 0.9	8.12 g/L/h	30 m liquid height	602 h <sup>-1</sup>
		80% conv	633 h <sup>-1</sup>
		95% conv	751 h <sup>-1</sup>
CO mass transfer capacity between 7 and 8.5 g/L/h		Expectation	
		$k_L a$ between 600 and 750 h <sup>-1</sup>	

Figure A.1: Preliminary calculations based upon publicly available data to estimate the CO mass transfer capacity ( $MTC$ ) and  $k_L a$  from the LanzaTech syngas fermentation process.

Table A.1: Parameters and variables for determining  $k_L a$  via the relationships in Table 2.1. 1: calculated using [25] for EL-GLRs. 2: calculated using [114]. Flow rates for one EL-GLR.

Variable	Symbol	Value	Unit
Riser diameter	$D_r$	5	m
Riser surface area	$A_r$	20	m <sup>2</sup>
Downcomer diameter	$D_d$	1.5	m
Downcomer surface area	$A_d$	1.8	m <sup>2</sup>
Dispersion height	$H_D$	25	m
Headspace pressure	$p_{\text{head}}$	101325	Pa
Bottom pressure	$p_{\text{bot}}$	344949	Pa
CO inflow	$\dot{n}_{\text{CO,in}}$	136	kmol <sub>CO</sub> h <sup>-1</sup>
Syngas composition	$y_i$	50% CO, 50% N <sub>2</sub>	mol <sub>i</sub> mol <sub>G</sub> <sup>-1</sup>
Syngas molar inflow	$\dot{n}_{G,\text{in}}$	272	kmol <sub>G</sub> h <sup>-1</sup>
Gas molar volume at bottom	$V_{G,m,\text{bot}}$	0.0075	m <sup>3</sup> mol <sub>G</sub> <sup>-1</sup>
Syngas inflow	$F_{G,\text{bot}}$	2031	m <sup>3</sup> h <sup>-1</sup>
Superficial gas velocity	$u_{G,s,\text{in}}$	0.028	m s <sup>-1</sup>
Power-to-volume ratio <sup>1</sup>	$P/V_D$	257	W m <sub>L</sub> <sup>-3</sup>
Gas hold-up <sup>2</sup>	$\varepsilon_G$	0.126	m <sub>G</sub> <sup>3</sup> m <sub>L</sub> <sup>-3</sup>
Liquid hold-up	$\varepsilon_L$	0.874	m <sub>L</sub> <sup>3</sup> m <sub>L</sub> <sup>-3</sup>
Concentration of solids	$c_{\text{solids}}$	0	kg m <sub>L</sub> <sup>-3</sup>
<i>Physical constants</i>			
Universal gas constant	$R$	8.314	J mol <sup>-1</sup> K <sup>-1</sup>
Gravity	$g$	9.81	m s <sup>-2</sup>
Density	$\rho_L$	993.37	kg m <sub>L</sub> <sup>-3</sup>
Temperature	$T$	310.15	K
Broth viscosity	$\eta_L$	$7.074 \times 10^{-4}$	Pas
CO diffusion coefficient	$D_{L,\text{CO}}$	$2.71 \times 10^{-9}$	m <sup>2</sup> s <sup>-1</sup>
Surface tension	$\sigma$	0.072	N m <sup>-1</sup>

Table A.2: Dimensionless numbers used for the determining  $k_L a$  in the relations given in Table 2.1, based on the definitions proposed by [25].

Name	Equation	Estimated value
Schmidt	$Sc = \frac{\eta_L}{\rho_L D_{L,\text{CO}}}$	~260
Eötvös	$Eu = \frac{\rho_L g D_r^2}{\sigma}$	~ $3.38 \times 10^6$
Galileo	$Ga = \frac{\rho_L^2 g D_r^3}{\eta_L^2}$	~ $2.40 \times 10^{15}$
Froude	$Fr = \frac{u_{G,s,\text{in}}^2}{g D_r}$	~ $40 \times 10^{-3}$
Reynolds	$Re = \frac{\rho_L u_{G,s,\text{in}} D_r}{\eta_L}$	~ $1.9 \times 10^5$
Sherwood	$Sh = \frac{k_L D_r}{D_{L,\text{CO}}}$	-

**Table A.3:** Results of the mesh refinement study.  $k_L a$  and  $MTC$  (100 s time-averaged) were determined for the three meshes with three different  $k_L$ -relations from Table 2.2. For the calculations, bubbles of 3 mm diameter were assumed as well as the hold-up increasing effect of ethanol and operation at 37 °C.

	Mesh 1		Mesh 2		Mesh 3	
Cells	370764		1688085		1929575	
Relation	$k_L a$ (h <sup>-1</sup> )	$MTC$ (gL <sup>-1</sup> h <sup>-1</sup> )	$k_L a$ (h <sup>-1</sup> )	$MTC$ (gL <sup>-1</sup> h <sup>-1</sup> )	$k_L a$ (h <sup>-1</sup> )	$MTC$ (gL <sup>-1</sup> h <sup>-1</sup> )
1	672	5.86	624	5.68	620	5.69
2	688	5.82	637	5.68	632	5.70
5	480	4.13	461	4.30	469	4.35

**Table A.4:** Discretization schemes and relaxation factors used for the different CFD models. The gradient was solved via the least-square cell-based scheme.

Variable	Pilot-scale		Large-scale	
	Discretization scheme	Relaxation factor	Discretization scheme	Relaxation factor
Pressure	PRESTO!	0.3	PRESTO!	0.3
Density	First order upwind	1.0	First order upwind	1.0
Body Forces	-	1.0	-	1.0
Momentum	Second order upwind	0.2	First order upwind	0.7
Volume fraction	First order upwind	0.5	First order upwind	0.5
Turbulent kinetic energy	First order upwind	0.5	First order upwind	0.8
Turbulent dissipation rate	First order upwind	0.5	First order upwind	0.8
Turbulent viscosity (eq.)	-	1	-	1
Tracer mass fraction	First order upwind	1	-	-

**Figure A.2:** Meshes used for CFD modelling. a) the mesh for the pilot-scale reactor model (grid size = 0.008 m). b-d) meshes for the industrial EL-GLR (grid size = 0.20 m, 0.15 m, 0.10 m, respectively).

**Figure A.3:** Dynamic variations in gas hold up and axial liquid velocity at the EL-GLR riser centreline at several axial positions. Full line: transient values; dotted lines: rolling averages; dashed lines: 200 s time-averaged values.

**Table A.5:** Results from the pilot-scale reactor used by Young et al. [139] and the predictions made by the CFD model. Given are the average values and the standard deviation along the radial direction, as well as the relative difference in the value as predicted by the CFD model.

**Figure A.4:** Influence of the absolute headspace pressure on MTC (Equation 2.7) and power consumption [113] by the compressor. b) Relation between the relative increases in compressor power consumption and MTC. MTC and  $P_{comp}$  are compared to a base-case with 101 kPa headspace pressure, considering that the gas-inflow rate is increased proportional to the headspace pressure to obtain constant  $k_L a$ .

**Table A.6:** For two sparger configurations,  $k_L a$  and MTC are compared for three  $k_L$  relations. Provided are the 200 s time- and volume-averaged values, while the difference was calculated relative to the bottom-plate sparger. Assumed are  $d_b = 3$  mm, a 30% increase in gas-hold up compared to water due to the presence of ethanol and a temperature of 37 °C. The gas hold-up in the configuration with sparger above the downcomer was calculated to be 11% lower, explaining the difference in  $k_L a$  values

	Bottom sparger		Higher sparger		Difference (%)	
	$k_L a$	MTC	$k_L a$	MTC	$k_L a$	MTC
	( $\text{h}^{-1}$ )	( $\text{gL}^{-1} \text{h}^{-1}$ )	( $\text{h}^{-1}$ )	( $\text{gL}^{-1} \text{h}^{-1}$ )	( $\text{h}^{-1}$ )	( $\text{gL}^{-1} \text{h}^{-1}$ )
Higbie [127]	673	5.84	503	4.59	-10.8	-6.22
Calderbank and Moo-Young [128]	689	5.86	515	4.61	-10.9	-6.20
Lamont and Scott [131]	485	4.18	376	3.37	-7.49	-3.95

**Figure A.5:** Surface plots at the  $zy$ -plane ( $x=0$ ) of the EL-GLR with the sparger 0.5 m above the downcomer outlet, a) the 200 s time-averaged gas hold-up, b)  $k_L a$  and c)  $MTC$  as determined via the Higbie relation, assuming  $d_b = 3$  mm, a 30% increase in gas hold up and a temperature of  $37^\circ\text{C}$

## CFD simulations with higher positioned sparger

### Methods

An alternative geometry has been developed with the spider sparger (Figure 2.1b) positioned 0.5 m above the downcomer outlet, and meshed with 370,000 cells and 0.3 orthogonal quality. In ANSYS Fluent, interpolation has been performed using the established flow field from the bottom-plate sparger (replace zone-option). Initialization has been performed by setting all directions of the liquid and gas velocities as well as the gas hold-up to zero, at 0.5 m above and below the sparger. Convergence (residuals  $< O(10^{-3})$ ) was obtained with the following time stepping strategy: 0.01 s for 2 time steps, 0.02 s for 5 steps, 0.05 s for 5 steps and was then increased to 0.1 s, while decreasing the momentum under-relaxation factor to 0.4 (raised back to 0.7 after 120 s). Results were obtained by exporting data for 200 s (every 2.5 s) after 350 s simulation time, when a stable flow field was obtained.

### Cultivation strategies and media composition

Fermentation broth 1 was effluent resulting from a CO fermentation by *Clostridium autoethanogenum* (DSM 10061) in a continuous stirred-tank reactor (CSTR). The cultivation was carried out in a 1.5 L glass jacketed chemostat (Applikon, The Netherlands) with a working volume of 1 L. The temperature was controlled at 37 °C, the agitation rate was set to 500 rpm and the pH was maintained at 5.9. The bioreactor was continuously supplied with a gas phase consisting of CO (6 mL min<sup>-1</sup>) and N<sub>2</sub> (6 mL min<sup>-1</sup>). The sterile growth media (composition reported in Table B.2) was supplied continuously at the dilution rate of 0.024 h<sup>-1</sup>. The fermentation effluent was continuously sparged with 100% N<sub>2</sub> to maintain anaerobic conditions, kept at room temperature (~20 °C) and collected anaerobically in a glass bottle during 4 days, and then used for the mass transfer experiments.

Fermentation broth 2 was the effluent resulting from CO fermentations by *C. autoethanogenum* (DSM 10061) in a custom-built rotor-stator spinning disc reactor (RS-SDR) coupled to a buffer tank. The fermentation broth was cultivated in a 600 mL glass mixed buffer vessel (300 mL working volume) and recirculated through the RS-SDR (60 mL working volume), made of polymethyl methacrylate. The reactor was operated in a sequential batch mode, with a cycle time of 24 hours. Each cycle, 10 mL of fermentation broth in the buffer tank was exchanged by the same volume of fresh sterile feed medium (composition reported in Table B.2). The headspace of the buffer tank (300 mL) was completely refreshed with 100% CO once a day and kept at 1.5 bar of absolute pressure. The buffer tank was placed on a heating stirring plate. The temperature was controlled between 35 and 37 °C, the broth was agitated at 200 rpm with a magnetic stirrer and the pH was maintained between 5.3 and 5.8. The fermentation broth was recirculated through the RS-SDR at a recirculation liquid flow rate of 120 mL min<sup>-1</sup>. The RS-SDR operated at varying rotation speeds (100, 500, 1000 or 1500 rpm). After 72 hours of cultivation, the fermentation effluent was collected in 1 L plastic bottles and stored in the fridge (~2 °C). The effluent of 8 consecutive independent fermentations was stored (during a maximum 4 weeks), mixed and then used for the mass transfer experiments.

Fermentation broth 3 was the effluent of a mixed culture converting CO into H<sub>2</sub> and acetate in a continuous stirred tank reactor (CSTR). The cultivation was carried out in a 500 mL chemostat with a working volume of 400 mL. The temperature was controlled at 30 °C, the agitation rate was set to 800 rpm and the pH was maintained at 7.0. The bioreactor was continuously supplied with a gas phase consisting of CO (2 mL min<sup>-1</sup>), N<sub>2</sub> (1.06 mL min<sup>-1</sup>) and CO<sub>2</sub> (0.27 mL min<sup>-1</sup>). The sterile growth media (composition reported in Table B.2) was supplied continuously to maintain the dilution rate of 0.014 h<sup>-1</sup>. The fermentation effluent was collected anaerobically into 1 L serum glass bottles sealed with butyl rubber stoppers and aluminium caps, under N<sub>2</sub>/CO<sub>2</sub> (80:20 v%) headspace, at 1.4 bar of absolute pressure. The effluent was stored at room temperature (~20 °C) during 5 days, and then used in the mass transfer experiments.

Fermentation broth 4 was produced by the fermentation of CO by *C. autoethanogenum* (DSM 10061) in batch bottles. The cultivation medium (which composition is reported in Table B.2) was dispersed into 1 L glass bottles (300 mL working volume) sealed with butyl rubber stoppers and aluminium caps. The headspace of each bottle (700 mL) was filled with 100% CO to a final absolute pressure of 1.5 bar, using an anaerobic gas-exchange system. The bottles were sterilised in an autoclave immediately after preparation, for 20 minutes at 121 °C. Each bottle was inoculated with 1% (v/v) of exponential growing inoculum, at initial pH of 5.9 and incubated without shaking at 37 °C until reaching optical density at 660 nm (OD<sub>660</sub>) of 0.2. The fermentation broth from each bottle was then collected and mixed, and used for bubble size characterisation (Figure B.1, Table B.3).

Bubble size method cross-validation

With broth-4, and in the same conditions as used with the other mixtures, bubbles were obtained that could be analysed using both methods (the one designed for the small bubbles with the photo-optical probe (SOPAT) and the one for the larger bubbles with the CANON EOS 200D camera). The resulting bubble size distributions (BSDs) are given in Figure B.1. As can be seen, the resulting BSDs are very similar, with the exception that the method used for the small bubbles is not able to capture bubbles bigger than 1.3 mm and that it has a slightly higher probability peak between 0.5 - 0.75 mm. As the obtained average bubble diameters, Sauter mean bubble diameters and standard deviations (Table B.3) were similar, it was concluded that both methods could be used for bubble size comparison purposes.

Figure B.1: Bubble size distributions obtained using the method designed for a) the smaller bubbles, and b) the larger bubbles.

Table B.3: Bubble diameter method cross-validation. For broth-4, the average bubble diameters, Sauter mean bubble diameter, and the standard deviation of the bubble diameter were determined via both methods.

## Supplement Chapter 4

**Figure C.1:** Mixing study in the EL-GLR. A tracer with the same properties as the fluid phase was injected at the outlet of the downcomer and its normalised concentration recorded at several positions in the riser (a, c – coordinates in m) and downcomer (b, d). The 95% mixing time  $t_m$  is obtained when all curves are within the dashed lines representing a 5% deviation around the final tracer concentration.  $t_m$  was recorded for a case without reaction (only the hydrodynamic model was enabled) (a, b) and a case including mass transfer and reaction at  $25 \text{ gL}^{-1}$  biomass without  $\text{CO}_2$  production (c, d).  $t_m$  without reaction is around 80 s, while with reaction it is around 115 s. This difference is explained by the lower gas hold-up in the case with reaction since the syngas is consumed. The circulation time  $t_c$  is estimated from the mixing time as  $t_m \sim 3 - 5 t_c$  [71].

## Statistical analysis of lifelines

It was determined how many lifelines were required to obtain statistically independent probability density distributions of the residence time in peaks and valleys. This was done by calculating the Kullback-Leibler divergence  $D_{KL}$  (Equation C.1) or the relative entropy for the variables of interest (e.g., the residence time distribution in peaks and valleys for CO and H<sub>2</sub>).  $D_{KL}$  is a common tool in data sciences to measure dissimilarity between two probability distributions [272]. By minimising  $D_{KL}$  of a distribution with respect to a given (“true”) distribution, it can be determined how close a distribution is to the true distribution [118, 272]. As a “true” distribution (with  $N_p, N_{t_c} \rightarrow \infty$ ) was not available, it was assumed that the distribution obtained with all peaks and valleys,  $P(N_p N_{t_c})_\infty$ , is sufficiently representative of the “true” distribution.

$$D_{KL}(P(N_p N_{t_c})_\infty || P(N_p N_{t_c})) = \sum_{i=1}^k P_i(N_p N_{t_c})_\infty \ln \left[ \frac{P_i(N_p N_{t_c})_\infty}{P_i(N_p N_{t_c})} \right] \quad (\text{C.1})$$

From the analysis became clear that with  $N_p N_{t_c} \sim O(10^5)$   $D_{KL}$  approaches zero (Figure C.2) for the probability distributions describing the duration of a peak in CO concentration. One could argue that even around  $\sim O(10^4)$  the information gain by extending the set of lifelines is small. These results give an indication of the required number of particles and run time for lifeline analysis of environmental fluctuations, which is considerably lower than the numbers typically applied for such analysis (e.g.  $O(10^6)$  [56, 57, 165]. As an exception, McClure et al. [200] only used  $\sim O(10^4)$  while obtaining statistically satisfactory results. It must be noted that our analysis is only applicable when particles act as passive tracers. When the simulated biomass particles affect the Eulerian flow or concentration

field (e.g., two-way coupling with metabolic models) [58, 99], a higher  $N_p$  is required to achieve a sufficiently homogeneous spatial biomass distribution [78]. In syngas fermentation modelling, this could be applicable if one wants to study the effect of local microbial  $\text{CO}_2$  production or consumption, using a detailed kinetic metabolic model.

By calculating  $D_{KL}$ , we saved a significant amount of simulation and data processing time: the analyses with 10 and 25  $\text{g L}^{-1}$  (650 s and 40,000 particles) only required 20 GB of data instead of 200 GB with the 5  $\text{g L}^{-1}$  case (1000 s and 160,000 particles). Next to checking whether the Lagrangian averages matches the Eulerian average [56], which is – in case of sufficient mixing – usually after 3 mixing times per particle, we suggest calculating  $D_{KL}$  as well to check variability of the results.

**Figure C.2:** Kullback-Leibler divergence  $D_{KL}$  determined using an increasing  $N_p N_{t_c}$  of the residence time distribution a) in a CO peak, b) CO valley, c)  $\text{H}_2$  peak, and d)  $\text{H}_2$  valley. Blue:  $D_{KL}$  obtained from distributions derived from lifelines with 5  $\text{g L}^{-1}$  biomass with  $(N_p N_{t_c})_\infty \sim 3 \times 10^6$ , green (10  $\text{g L}^{-1}$ ) and red (25  $\text{g L}^{-1}$ ) with  $(N_p N_{t_c})_\infty \sim 6 \times 10^5$ .

Figure C.3: Surface plots of the 200 s time-averaged gas hold-up in the  $zy$ -plane ( $x = 0$ ) of the EL-GLR, obtained with a)  $25 \text{ g}_L^{-1}$  biomass without  $\text{CO}_2$  production, b)  $25 \text{ g}_L^{-1}$  biomass while including  $\text{CO}_2$  production and c)  $2 \text{ g}_L^{-1}$  biomass without  $\text{CO}_2$  production.

Figure C.4: Variation of a) dissolved  $\text{CO}$  and b) dissolved  $\text{H}_2$  concentrations within the EL-GLR reactor volume in the cases without and with  $\text{CO}_2$  production (with  $25 \text{ g}_L^{-1}$  biomass). In the boxplot each quartile represents 25% of the dispersion volume with a specific concentration.

# Appendix D

## Supplement Chapter 5

### D.1. Detailed CRD model description

#### D.1.1. Metabolic kinetic model

The kinetic model describes the microbial biomass, six metabolites that are in exchange with the cellular environment (CO, H<sub>2</sub>, CO<sub>2</sub>, acetic acid, ethanol and 2,3-butanediol), and six intracellular compounds (formate, acetyl-CoA, intracellular acetate, reduced ferredoxin, NADH and NADPH). Transport across the cell membrane is regarded as instantaneous (i.e., the concentration of CO in the cell equals the concentration outside the cell and its import does not require energy), except for intracellular acetate, which is actively excreted while extracellular acetic acid passively diffuses back into the cell. The acid-base equilibrium of acetate is considered so that the total extracellular acetic acid concentration equals the dissociated acetate concentration and the undissociated acetate concentration ( $AcT = HAc + Ac^-_{IC}$ ). An overview of the metabolites, their reference concentrations, the provided initial concentrations and the minimum concentrations, which are required for model stability in case the concentrations get too low, are provided in Table D.1. The minimum concentrations prevent negative results of the ODE system, and were used in a correction scheme to prevent excessive rates in case lower concentrations were obtained.

With the lin-log based kinetic model, 11 intracellular rates were calculated (Table D.2), with which the metabolite pools were updated. These rates were calculated using a given set of reference concentrations and rates from the steady-state model, and a state-independent elasticity matrix (Table D.3) [40]. Some of the rates were considered irreversible, in line with their physical relation, to increase model stability and to prevent nonphysical model results.

For a given set of concentrations  $c_i$  in the particle (based upon their environment and history), the intracellular, lin-log corrected flux  $J$  (in  $\text{mol mol}_x^{-1} \text{h}^{-1}$ ) for reaction  $j$ , was calculated using Equation D.1, in which  $r_j^{ll}$  is the dimensionless lin-log-correction term. The back-diffusion rate of acetic acid into the cell was calculated using Equation D.2 (with the cell surface area,  $a_x$  ( $321 \text{ m}^2 \text{mol}_x^{-1}$ ), and the acetic acid diffusivity,  $k_{HAC,D}$  ( $3.8 \times 10^{-5} \text{ m h}^{-1}$ )). It should be noted that the lin-log formulation may decrease the accuracy of reaction rates far away from the reference concentration [236]. To minimise model exceptions, such as negative concentrations and excessive rates in such regions,

Table D.1: The metabolites and their characteristic concentrations for solving the CFD-CRD model.

Compound <i>i</i>	Reference concentration $c_i^{\text{ref}}$ (mol m <sup>-3</sup> )	Initial concentration $c_{i,0}$ (mol m <sup>-3</sup> )	Minimum concentration $c_{i,\text{min}}$ (mol m <sup>-3</sup> )

### D.1.2. Increasing the model stability

After calculation of the volumetric derivatives (Equations D.3 – D.14), their physical correctness is checked (i.e., is there enough metabolite/dissolved gas available). This is done by calculating a maximum rate, considering that the concentrations cannot be lower than the minimum one and that multiple Lagrangian particles could be present in the current volume element  $N_{p,VE}$ , decreasing the substrate availability per particle (this term is not included for the intracellular compounds).

This was done by calculating the maximum rate to be  $\left. \frac{dc_i}{dt} \right|_{\max} = \frac{c_i - 0.9c_{i,\min}}{N_{p,VE}\Delta t_{IC}}$  with  $t_{IC}$  as the integration time step of 0.1 ms, while a factor 0.9 was used to prevent zero-divisions when  $c_i = c_{i,\min}$ . In the case that for one of the other metabolites  $j$  the maximum rate is exceeded,  $\left. \frac{dc_j}{dt} \right|_{\max} > \left. \frac{dc_j}{dt} \right|_{\max}$ , the entire metabolism is proportionally scaled to maintain model stability without violation of the mass balance (Equation D.15). When for multiple metabolites the maximum rates are exceeded, this re-scaling is conducted based on the rate that had the smallest relative excess.

$$\frac{\left. \frac{dc_i}{dt} \right|_{\max}}{\left. \frac{dc_j}{dt} \right|_{\max}} = \frac{\left. \frac{dc_i}{dt} \right|_{\text{cor}}}{\left. \frac{dc_j}{dt} \right|_{\max}} \quad \text{thus} \quad \left. \frac{dc_i}{dt} \right|_{\text{cor}} = \left. \frac{dc_j}{dt} \right|_{\max} \cdot \frac{\left. \frac{dc_i}{dt} \right|_{\max}}{\left. \frac{dc_j}{dt} \right|_{\max}} \quad (\text{D.15})$$

After integration via the Runge-Kutta 4<sup>th</sup> order algorithm using a fixed integration time step  $\Delta t_{IC}$ , the viability of the results were checked by comparing the updated concentration with a predicted range of values determined by the forward Euler method. In case the new concentrations determined by the Runge-Kutta integration method are more than 100 times outside the predicted range from the forward Euler method, the concentrations are not updated (0.15% of the particles). In the case that computations caused invalid (nan) results (0.5%), then no changes in concentration were considered during that particle time step. These steps were required for solving the CFD-CRD model in a highly parallelised environment supercomputer with 128 CPU cores. Solving the model on a less parallelised system lasted significantly longer, but was computationally more stable.

From the obtained lifelines the rates could be back-calculated considering the modifications, by solving a system of linear equations. In this case the equations D.3–D.14 are considered as a system of linear equations, which could be solved for the reaction rates  $J_j$  using the known concentrations, stoichiometry's, and derivatives in MATLAB.

### D.1.3. Model verification as a batch process

Several simulations have been performed to check whether the implementation of the kinetic model in Ansys FLUENT was done correctly. The original kinetic model was written in MATLAB, then it was rewritten into C and subsequently adjusted to use with Ansys FLUENT's DPM\_SCALAR\_UPDATE macro. Its validity was checked by calculating the concentration trajectory in a 50 s liquid-phase “batch” fermentation from the initial concentrations (Table D.1), in MATLAB, the C code and the FLUENT code, for which simulations were performed in the Snellius supercomputing infrastructure. In C and FLUENT, the system was integrated using the Runge-Kutta 4<sup>th</sup> order algorithm as described above, while in MATLAB the system was integrated using ode15s.

From the metabolite trajectories (Figure D.1) became clear that there are two distinctive regions during the batch fermentation. In the first region (0 to ~3.5 s) all the models produced the same results and the model was found to be applicable to solve kinetic interactions. But in the other region, the lin-log model was found not to be applicable so that the results were determined by the imposed modifications. In order to prevent nonphysical results, the additional modifications imposed in the Ansys FLUENT script cause that nothing changes (the cell is on “stand-by”).

The ode15s solver in MATLAB was unable to provide results in the region with low concentrations. Although tests were done with other ODE solvers in the C-script (i.e., the explicit Runge-Kutta-Cash-Karp and the Bulirsch-Stoer algorithms with adaptive time stepping as well as the implicit Kaps-Rentrop and the semi-implicit extrapolation methods [273]), they did not increase stability in the region of instability, nor changed the results of the simulation during the first ~3.5 s. The poor validity of the lin-log model structure in regions with low concentrations, should be kept in mind when developing kinetic models that have to be coupled with CFD simulations.

The modifications imposed in the FLUENT script and the supercomputing infrastructure probably caused smaller deviations from the endpoint at 3.5 s, compared to the C-script, wherein larger acetate and H<sub>2</sub> consumption rates are predicted. The imposed minimum concentrations (min  $O(10^{-12})$ ), and the numerical error ( $O(10^{-16})$ ) can result into derivatives of  $O(10^4)$ , which might lead to excessive rates, which were in turn limited as much as possible using the rate-limitation mechanism described above.

Currently, experimental data regarding the impact of short-term (order of seconds) fluctuations on *C. autoethanogenum* metabolism are unavailable; such results are required to validate the model predictions under the simulated conditions. The kinetic model, was however, parameterised on an experimental data set with metabolic oscillations in the time-scale of hours [40, 204]. Our model predictions should thus be regarded as a hypothesis regarding cellular response under large-scale conditions, which are to be explored further.

**Figure D.1:** Verification of the model implementation strategies, by comparing metabolite concentration (in  $\text{mol/m}^3$ ) trajectories during a batch ( $t$  in s) fermentation in the liquid phase, with  $c_x = 5 \text{ gL}^{-1}$ . Based on the provided initial concentrations (Table D.1) the three implementations of the metabolic-kinetic models in MATLAB (green line), C (blue dashed line) and Ansys FLUENT (red line) were solved. The three models produce the same results in the uncoloured region (hence the overlapping lines), while the predictive capacity of the model becomes more limited in regions with lower metabolite concentrations (shaded with grey), where the MATLAB model was unable to provide results.

#### D.1.4. Lifeline reconstruction in C and comparison with constant concentration case

To check the influence of the computing infrastructure on the metabolite concentrations, a lifeline obtained from the CFD-CRD model, was reconstructed via the C-script (Figure D.2). The dissolved  $\text{CO}$ ,  $\text{H}_2$  and  $\text{CO}_2$  concentrations were used as input parameters for this model, as well as the local number of particles (required for the rate-limitation mechanism). As the data export resolution was 750 times higher than  $\Delta t_{\text{IC}}$ , linear interpolation between two subsequent data points was done. Generally, a pretty good overlap is observed between the CFD results (red) and the reconstructed CFD-results (black lines). Negligible deviations only occurred in the cases with very low dissolved gas concentrations for AcCoA, NADH and NADPH. This made us conclude that our modelling algorithms and workflow were well implemented and suitable for metabolism predictions on dissolved gas concentration fluctuations.

To inspect how the metabolite behaviour with  $2.5 \text{ gL}^{-1}$  biomass deviates from a case with constant dissolved gas concentrations, the model with constant dissolved gas concentrations was applied at the average  $\text{CO}$  concentration during that lifeline of  $0.29 \text{ mol m}^{-3}$ . Because the average  $c_{\text{L,CO}}$  is relatively high and its characteristic time was in the similar

order of magnitude as the mass transfer characteristic time, no large spatial gradient was expected in the CFD model. The causes that there is high similarity between the general trend from the CFD-CRD model results and the model with constant dissolved gas concentrations. The fluctuations in  $c_{L,CO}$  have strong effects on the metabolism, as can be seen by the depletion of formate and the increases in ethanol production during moments with low  $c_{L,CO}$ .

Figure D.2: Comparison of metabolic fluctuations during a lifeline ( $c$  in  $\text{mol m}^{-3}$  and  $t$  in s) from the CFD-CRD model (red), its reconstruction in C (black dashed line) and the constant concentration model (blue),  $c_x = 2.5 \text{ g L}^{-1}$ , with an average  $c_{L,CO}$  of  $0.29 \text{ mol m}^{-3}$ .

### D.1.5. Choice of $\Delta t_f$ and $N_p$

A considerate decision had to be made regarding the number of particles  $N_p$  which the kinetic model was solved for. Simulating more particles could increase accuracy of the solution, but would lead to longer simulations. The build-up of the simulation time per time step was determined for a varying number of particles for which the metabolic model was solved ( $N_p$  [0 - 250,000]) (Figure D.3a). Obviously, the simulation time of the flow, species, turbulence and particle displacement models were independent from the number of particles for which the metabolic model was solved for. The total time required to solve the metabolism, increased linearly with the number of particles. Per particle solving the CRD model took around 0.04 ms (with  $\Delta t_f = 5 \text{ ms}$  and 128 CPUs), which turned out to be the limiting mechanism in terms of simulation time. The cumulative CO and  $\text{H}_2$  consumption rates did not vary significantly with more than 80,000 particles. In order to test the accuracy of the simulation results with respect to the number of particles and the Eulerian time step  $\Delta t_f$ , the CO and  $\text{H}_2$  uptake rates (volume integral of Equation

**Figure D.3:** The influence of the number of simulated particles on simulation time and accuracy. a) The built-up of the simulation time per Eulerian time step ( $\Delta t_f$ ) as a function of the number of particles for which the metabolic model was solved. The influence of the number of particles on the b) total CO and c)  $H_2$  consumption rate. The data was obtained using  $\Delta t_f$  of 5 ms and 250,000 well-distributed Lagrangian particles, during 200 flow time steps at 128 CPU cores. FLUENT: leftover between the total wall time and the provided simulation times for all the sub-models, attributed to communication and parallelisation gains and losses; Other models: the species model (for CO,  $H_2$  and  $CO_2$ ), gas-liquid mass transfer and the turbulence models; Particles: displacement of the 250,000 particles, which time was determined by not solving the metabolism.

5.1, in  $\text{kg s}^{-1}$ ) were determined for the cases with 80,000 and 250,000 reacting particles, with varying time steps (1 - 10 ms) (Figure D.3b,c). From the analysis became clear that the accuracy increase between 80,000 and 250,000 particles is very limited, compared to the twofold increase in computation time, rendering it unworthy to use more than 80,000 particles. From the time step variation, the inverse proportional relationship with run time became visible, and consequently we chose to use a 5 ms time step, since that one showed low variations in uptake rates, for an acceptable simulation time.

Large deviations were expected between the uptake rate predicted by the metabolic model at the beginning of the Eulerian time step,  $\left. \frac{dc_i}{dt} \right|_{p,t}$ , and the one that has been realised at the end of  $\Delta t_f$ ,  $\left. \frac{c_i|_{t+\Delta t_f} - c_i|_t}{\Delta t_f} \right|_p$ , in case of large time steps (since  $\Delta t_f \gg \Delta t_{IC}$ ). Since the species balances are only calculated at the beginning of the flow time step, and not while solving the metabolic model, one has to be sure that the deviation between these becomes not too big. Using as source term would not guarantee intracellular mass balance closure, and could lead to unstable solutions in cases with low metabolite con-

centrations. Instead, the cumulative integration term in the source term guarantees mass balance closure and increases model stability, but requires the use of smaller  $\Delta t_f$ . To test the choice of  $\Delta t_f$ , the average percentage of deviation between the two approaches was determined for the examined range of  $\Delta t_f$  (Equation D.16, Figure D.4). The deviations were considered to be small enough ( $< 10\%$ ) using a 5 ms time step.

$$\text{deviation}(\%) = \frac{1}{N_p} \cdot \sum_{p=1}^{N_p} \left\| \frac{\frac{dc_i}{dt}\big|_{p,t} - \frac{c_i|_{t+\Delta t_f} - c_i|_t}{\Delta t_f}}{\frac{dc_i}{dt}\big|_{p,t}} \right\| \cdot 100\% \quad (\text{D.16})$$

**Figure D.4:** Influence of the Eulerian time step and the number of particles for which the kinetic model is solved on a) the accuracy and run time of the CFD-CRD and c) the mass balance deviation. Accuracy was measured as a) the CO-uptake rate (blue) and b) the  $H_2$  uptake rate (red), while run time (black) was determined as time taken per second simulation time. The mass balance deviation was calculated using Equation D.16. Squares and circles denote the simulations with 250,000 and 80,000 reacting particles, respectively. All uptake rates and run times were based on their average during 0.2 s simulation time.

### D.1.6. Mass balance during a lifeline

The carbon and electron balances were computed during lifelines for each  $c_x$  case, and analysed as a function of the temporal  $c_{L,CO}$  (Figure D.5) in order to determine the mass balance error due to the model correction terms. Generally, the mass balance closes each moment in time, although at low concentrations (the dashed region) there is some intracellular formate generation (see Section 5.3.1).

**Figure D.5:** a, c, e) Carbon and b, d, f) electron balances during varying  $c_{L,CO}$  of a lifeline for varying  $c_x$ : a, b) 2.5; c, d) 3.75; e, f) 5 g L<sup>-1</sup>. The shaded area below the calibrated  $c_{L,CO}$  range. The metabolite rates (colouring in legend) were sorted along their respective  $c_{L,CO}$  and smoothened using smoothing factor 0.4 for improved visualisation.

# D.2. Relationship between dissolved CO and H<sub>2</sub>

**Figure D.6:** Relationship between  $c_{L,CO}$  and  $c_{L,H_2}$ . The scatters represent the average  $c_{L,CO}$  and corresponding  $c_{L,H_2}$  for 4000 lifelines for each biomass concentration. The resulting linear approximations were determined using linear regression in MATLAB and checked by calculating  $R^2$ .

**Table D.4:** Cases for which the CRD model with constant dissolved gas concentrations was solved for. The CO concentration was varied in a specific range for each biomass concentration, which resulted in a corresponding H<sub>2</sub> concentration. The CO<sub>2</sub> concentration was kept as a constant value, based on its time- and volume-averaged concentration in the EL-GLR during the last 900 seconds of the CFD-CRD simulation.

$c_x$ (g L <sup>-1</sup> )	$c_{L,CO}$ range (mol m <sup>-3</sup> )	$c_{L,H_2}$ (mol m <sup>-3</sup> )	$c_{L,CO_2}$ (mol m <sup>-3</sup> )
5	0.005 — 0.05	$1.99 c_{L,CO} + 0.074$	21.4015
3.75	0.05 — 0.12	$1.43 c_{L,CO} + 0.110$	17.5929
2.5	0.125 — 0.35	$0.846 c_{L,CO} + 0.0885$	24.5735

**Figure D.7:** Comparison of uptake rates for CO and H<sub>2</sub> between the CRD model (Metabolic model) and the steady-state (Monod and Haldane) models as a function of their concentration in the liquid phase. Black line: steady-state kinetics (Table 4.1); dashed black line:  $K_S$  according to the steady-state model; coloured dashed lines: results from CRD model with constant dissolved gas concentrations.

### D.3. CO and H<sub>2</sub> uptake kinetics and inhibition by ferredoxin

From the models with constant dissolved gas concentrations,  $q_{CO}$  and  $q_{H_2}$  were determined as function of the dissolved gas concentration (Figure D.7) (considering the ratio between CO and H<sub>2</sub> (Figure D.6)). The CO-uptake rate in the CRD model is slightly higher than the one in the case of Haldane kinetics. The inhibition effect at increased  $c_{L,CO}$  is not visible in the CRD model. The H<sub>2</sub>-uptake rate is clearly lower than was predicted with the Monod model, and an inhibition effect due to increased  $c_{L,CO}$  (and  $c_{L,H_2}$ ) was observed.

From the lifeline results in the CFD-CRD model, was derived that inhibition of CO- and H<sub>2</sub>-uptake could occur due to high concentrations of reduced ferredoxin (Figure D.8). When  $c_{Fd_{red}^{2-}}$  is around 5 mol m<sup>-3</sup>,  $q_{H_2}$  starts to decrease significantly, which could indicate a certain inhibition mechanism by reduced ferredoxin. The spread that is observed in the H<sub>2</sub> and CO data regarding H<sub>2</sub>-uptake at high concentrations, suggests that the inhibition effect is not directly caused by the CO and H<sub>2</sub> concentrations themselves.

**Figure D.8:** Relationships between a) dissolved CO and b)  $\text{H}_2$  concentration, the reduction state of the cell ( $c_{\text{Fd}_{\text{red}}^{2-}}$ ), and the uptake rate of the respective gas  $q_i$ . The scatters mark temporal observations during a lifeline from the CFD-CRD simulation with  $c_x = 5 \text{ g L}^{-1}$  (between 100 and 1000 s), the scatter density denotes its probability of occurrence,  $c_{L,\text{CO},\text{max}} = 0.25 \text{ mol m}^{-3}$ ,  $c_{L,\text{H}_2,\text{max}} = 0.42 \text{ mol m}^{-3}$ ,  $c_{\text{Fd}_{\text{red}}^{2-},\text{max}} = 11.25 \text{ mol m}^{-3}$ . Shaded areas mark zones with  $c_{L,\text{CO}} < 0.025 \text{ mol m}^{-3}$ .

## D.4. Formate production

**Figure D.9:** The relationship between a)  $c_{\text{Fd}_{\text{red}}^{2-}}$  and b)  $q_{\text{H}_2}$  and the formate concentration. The scatters mark temporal observations during a lifeline from the CFD-CRD simulation with  $c_x = 2.5 \text{ g L}^{-1}$  (between 100 and 1000 s), their density denote the probability of occurrence.

## D.5. Ethanol production during lifelines

Figure D.10: Comparison of lifeline-averages from the CFD-CRD model (after removing  $c_{L,CO} < 0.025$  mol m<sup>-3</sup>) with the constant concentration model and experimental data. The average biomass-specific rates and yields are plotted against the average  $c_{L,CO}$ : a)  $q_{CO_2}$ , b)  $q_{AcT}$ , c)  $q_{EtOH}$ , d) the electron-to-ethanol yield  $q_{EtOH}/q_{e^-}$  ( $q_{e^-} = 1/2(q_{CO_2} + q_{H_2})$ ), and e) the acetate-per-ethanol ratio  $q_{AcT}/q_{EtOH}$ . The scatters, with varying transparency to reduce overplotting, represent 900 s averages for ~4000 lifelines for each  $c_x$  simulation (blue 2.5; green 3.75; yellow 5 g L<sup>-1</sup>), the dashed line simulations with constant dissolved gas concentrations at the indicated biomass concentrations, and the markers reconciled [218] experimental chemostat data: ◆ [44]; ■ [46] (CO<sub>2</sub>); • [45]; ▲ [90]; ▼ [46] (CO<sub>2</sub>); ▲ [45].  $c_{L,CO}$  in ▲ [89], was estimated using their provided  $k_L a$ .

Figure D.11: Relationship between  $q_{H_2}$ -uptake and  $q_{EtOH}$ . The scatters, with varying transparency to reduce overplotting, represent 900 s averages for ~4000 lifelines for each  $c_x$  simulation (blue 2.5; green 3.75; yellow 5  $g L^{-1}$ ), the dashed line simulations with constant dissolved gas concentrations at the indicated biomass concentrations, and the markers reconciled [218] experimental chemostat data:  $\blacklozenge$  [44];  $\blacksquare$  [46] (CO + H<sub>2</sub>);  $\bullet$  [46] (CO);  $\blacktriangle$  [90];  $\blacktriangleright$  [45].  $c_{L,CO}$  in  $\blacktriangleleft$  [89], was estimated using their provided  $k_L a$

Figure D.12: Relationship between the growth rate  $\mu$  and  $q_{EtOH}$  and  $q_{AcT}$ . The scatters mark temporal observations during a lifeline from the CFD-CRD simulation with  $c_x = 3.75 g L^{-1}$  (between 100 and 1000 s), their density denotes the probability of occurrence.

Table D.5: Catabolic reactions towards ethanol and acetate production from CO, including the Gibbs free energy at standard conditions per mol product and CO [84].

Reaction		$\Delta_r G^o$ (kJ mol <sup>-1</sup> <sub>product</sub> )	$\Delta_r G^o$ (kJ mol <sup>-1</sup> <sub>CO</sub> )
Acetogenesis	$-4\text{ CO} - 2\text{ H}_2\text{O} + \text{C}_2\text{H}_3\text{O}_2^- + \text{H}^+ + 2\text{ CO}_2$	-135.04	-33.76
Solventogenesis	$-6\text{ CO} - 3\text{ H}_2\text{O} + \text{C}_2\text{H}_5\text{OH} + 4\text{ CO}_2$	-224.66	-37.44
Starvation	$-2\text{ CO} - \text{C}_2\text{H}_3\text{O}_2^- - \text{H}^+ - \text{H}_2\text{O} + \text{C}_2\text{H}_5\text{OH} + 2\text{ CO}_2$	-89.62	-44.81

D.6. Metabolism

Figure D.13: Metabolism of *C. autoethanogenum* during large-scale syngas fermentation. 100 seconds of a lifeline of the case with 2.5 g<sub>x</sub> L<sup>-1</sup> is shown with its concentration (in mol m<sup>-3</sup>) and rate (in mol mol<sub>x</sub><sup>-1</sup> h<sup>-1</sup>) fluctuations. Pool sizes and arrow thickness are approximative to the median concentrations and rates during the whole lifeline.

Figure D.14: Metabolism of *C. autoethanogenum* during large-scale syngas fermentation. 100 seconds of a lifeline of the case with  $5 \text{ g}_\text{x} \text{ L}^{-1}$  is shown with its concentration (in  $\text{mol m}^{-3}$ ) and rate (in  $\text{mol mol}_\text{x}^{-1} \text{ h}^{-1}$ ) fluctuations. Pool sizes and arrow thickness are approximative to the median concentrations and rates during the whole lifeline.

# Acknowledgements / Dankwoord

A PhD thesis is not just the accumulated written work of one single person working at one single place. This thesis was written not only behind a (standing) desk in an office, but also in several other places: first at home, during the pandemic, but also in other places, on trains, and planes: in Germany, France, Denmark, Australia and even in a crappy hospital in Liège on a Saturday night. I'm grateful for the advances in modern technology, which enabled running multi-gigabyte simulations from the WiFi on ICE. And then I did not even mention the help obtained from ChatGPT.

But most importantly, finishing a PhD is not a lonely achievement. During the last few years, many people were involved in various ways, probably too many to count, but I would like to start by thanking the people mostly involved:

**Henk**, you are a true visionary in the field of bioprocess engineering, which has been a great inspiration to me while working together over the past few years. You successfully familiarised the international biotech community with the 'start with the end in mind' mentality. I am very grateful to have been able to work on your ideas and apply them to gas fermentation. All your feedback and advice has helped me to grow and be the best that I can be.

**Cristian**, when you were teaching the NMST, you lured me into modelling and then into this PhD position. During the PhD I really enjoyed teaching the NMST together and discussing any programming problem. I still think it is a pity that you left TU Delft after the first year, but despite the geographical distance we stayed in touch. While going through your latest paintings and snorkelling experiences, we were met regularly for lunch and a good cup of coffee. Thank you so much for getting me excited about this field and all the great times we have had together.

**Cees**, I am so glad that you came on board. Not only is your technical guidance of superior quality, also your involvement in the other aspects of the PhD has been valuable. It has been a pleasure to work together and to see the CASE group grow and develop over time. Not only professionally but also on a more personal level, we have had great times. You have become not only an excellent supervisor and co-promotor, but also a friend. Thank you again for inviting us to your wedding on Terschelling. That weekend was the highlight of 2023 and will be remembered forever.

Thank you all for your great contributions to this thesis and all the other feedback, hints and advice you provided. This enabled us to share our work in papers and in many conference talks. I am grateful for all the presentations I could give, with special mention to the one on Heron Island. Thanks for making this once-in-a-lifetime journey possible!

Marina and Eduardo were my closest colleagues during my PhD. **Marina**, without your enthusiasm for science and gas fermentation, and the way you passed it on to me, I might never have started this adventure. I am still very proud of how, in a 30-minute meeting, we combined our skills and wrote a research proposal. A few months later we got it published. We enjoyed many trips and conferences together, we had great times in nightclubs in Nottingham, in the forests near Wageningen, and watching the sunset on the Rheintreppe in Düsseldorf. Thank you for welcoming me to Novozymes and the cold in Copenhagen. It has been a pleasure working with you over the past five years.

**Eduardo**, thanks for the f\*cking model! We have had so much trouble getting it to work and with the analyses, but now we have a cool movie to show. Your love-hate relationship with science is adorable, and your critical attitude towards thermodynamic analyses of metabolic pathways is next level. I have loved the discussions we have had over the last couple of years. We always helped each other to improve our work, but we'll never agree on some philosophical theories (like degrowth). Let's continue discussing them while watching some small bubbles rise.

On a day-to-day basis, **Sam**, you got me through my PhD. I should have spent a bit more energy listening to your cricket stories, as you listened to all my complaints about whatever model did not work. We had a great time living together at the Arthur van Schendelplein, with the traditional *ambachtelijke knakworstlunch* as highlight of the weekend. I will always feel guilty for not being able to attend your defence. Thank you for all your support and friendship.

Thank you, **Sam** and **Marina**, for being my paranymphs. I hope both of you are not spending too much time on it, but I'm sure it will be a day we'll never forget.

**Steven**, thanks for all the discussions on the wording of the propositions. As the in-house philosopher you taught me the basics how to become one.

Many students worked during their MSc or BSc thesis on topics related to this thesis. First of all, **Britt**, you did a wonderful job by starting up the project, I'm glad that we kept in touch during the last few years. **Héctor**, it was a pleasure to lure you into the project and later into a PhD. It was great working with you, first as a student and then as a colleague. We had amazing discussions (with and without carbonated liquids) and rainy bike rides during which we learnt a lot from each other. I am looking forward to meeting the new colleague you will have to recruit as CFD BOSS 3.O. **Lilo**, you started your project just after a lockdown, your enthusiasm was infectious and pushed the project forward: I'm very proud we got your results published. **Laura**, **Yassine**, **Bram** and **Lucy**, I would also like to thank you for the great time we had during your projects. Coaching and supervising all of you was one of the most enjoyable parts during the PhD.

It has been wonderful to be part of the BPE group. As a group we have done so much together: No group or company could ever compete with such a great working environment. Everyone in the group went through similar highs and lows (some higher, some lower), and sharing these experiences (or: *lifelines*) together paves the way for lifelong friendships. I'm glad to have shared all of these with such a fantastic group of colleagues. During our working days we had many (and perhaps too long) coffee and lunch breaks, usually with snacks or cakes after birthdays or conference trips. It's a shame that some of the breaks were cut short because of ongoing discussions about the monarchy. After work, we ordered beers via Flink, we organised BBQ's, we went to the beach, we (tried to) brew beer, we went out for bike rides, we celebrated birthdays and we even had a month-long beard growth competition, after eating Mexican food with our nasty moustaches.

During this time, I shared the office with Joan, Marina, Rik, Héctor and Tamara. I'm thankful to all of you that I could ask whatever random question that was in my mind. **Joan**, you were an example how to approach the PhD, and I'm glad that your roadmap through Manuscript Earth is still there in the office. **Marina**, we managed to keep each other in the office for way too long to discuss mass transfer limitations or whatever other interesting problem one of us faced. **Rik**, you did a wonderful achievement by convincing me to share code online. I highly enjoyed the discussions we had in the office on whatever topic, ranging from bubbles and broth to the credibility of the executive board. Thanks for all the help in writing code, improving figures and analysing metabolic fluxes. **Héctor**, I enjoyed welcoming you in the office as a colleague, maybe you will become *officemeister* once again. You are such a kind and helpful person. I highly enjoyed organising the many BBQ's together. **Tamara**, you are a scientific bulldog, please take some time to enjoy and reflect on your achievements. Time flew by during our drive back from Enschede, especially with all the nice conversations we had.

Marijn and Oriol, the MES-twins, I hope both of you can celebrate ending this period in good health as soon as possible. We had great parties together, for example after King's Day when you met "the Koning van Delluft". **Oriol**, I loved to discuss and to share the frustrations on COMSOL-modelling together. Let's hope that Catalunya will gain independence soon. It was great spending time together, **Marijn**, when we went to PSV, to Liberation day, or just to Pint Wednesday in de Gist. Next to one of the kindest persons, you are also one of the craziest persons ever: With the same ease as you walk through glass doors, you walked from Wageningen to Veenendaal.

**Mariana**, you are the living proof that a monarchy actually works, you gained democratic legitimacy as BPE Queen. Thanks for luring me into the PhD committee. **Tiago**, you resemble drive and persistence: it's inspiring to see how you get things done. This is not only demonstrated in the never-ending discussions we had on topics ranging from chromatography modelling, to monarchy and communism, but also by you flying

back-and-forth from Milan to celebrate King's Day in Amsterdam. Thanks for all the discussions, your help and advice.

**Daphne**, as travel buddies we started our holiday's together, after going through the same experiences in the last few months. It was great to follow all your adventures, I'm sure more will come. **Roxana**, thanks for all the nice times we had together, your kindness and patience, for example after the first Oktoberfest party. Herzlichen Dank für deine Hilfe bei den vielen Übersetzungen, ohne dich hätte ich nie gewusst, was eine Blasensäule ist. **Maarten**, you are one of the most practical guys of the group, I love to hear your innovative solutions to some problems. I'm always looking forward to hearing more about your 3D printed Arduino projects. **Tim**, you undergo a transformation after a few drinks, luckily you only drink from small glasses. Thanks for all the sweets you brought to the coffee breaks.

At some point, Cees started hiring like crazy and we ended up with the CASE group. It was amazing to see this group starting to form and to have biweekly meetings, dinners, activities and trips together with the young research group. **Ramon**, thanks for all your efforts in organising the meetings. You kickstarted your PhD with amazing work and you are well on track to give more presentations than me, including an amazing one in Boston to look forward to. **Mariana** and **Miki**, we had great times, from Terschelling to Stuttgart, we had fun. "Well, that's good for you".

**Victor**, you're a bit of a geographical outlier to the group, but definitely part of it. Thanks for introducing me to DTU and your colleagues and friends, and going out to the sauna, football matches or your neighbours party. I loved the sudden discussions we had on a wide range of topics spanning from CFD modelling to politics.

Meanwhile BPE kept on growing. New faces provide new identities to the group, while keeping older ones. For example, last year the activities committee lifted the Oktoberfest to the next level. Thanks **Maarten**, **Brenda** and **Marika** for keeping such traditions alive. I wish everyone who still has to finish all the best and lots of luck, I am sure we will stay in touch!

I would like to thank **Adrie** for some great dinners, for working together on several projects, and sometimes you were even the first to read my work. I felt a bit sorry all the time to ask for money and other bureaucracies. **Ludo**, it was amazing spending time together in Berlin, your love for your technology is highly motivating and a driver to continue working on whatever you feel you're interested in. Thanks **Rob**, for the sometimes way too lengthy discussions about bubbles. **Kawieta**, for all the logistics to keep our group up and running.

Prior to the defence I want to thank the committee for reading the thesis, with special mention to **Ralf** for the great discussions we had on Heron Island. Surely you gave me the opportunity to present in many conferences, from which I learnt a lot.

My friends, for their support during this whole journey. In particular, **Koen, Berend, Hessel**, for the great times near the Russian border fence close to Danzig. Let's plan another weekend soon. **Marijn**, for watching rising bubbles in broken beer glasses in Stuttgart. **Lennart, Thijs** and **Steven**, for ice skating every Tuesday night.

Maar zonder jullie, **papa en mama**, had ik dit nooit geschreven. Heel erg bedankt voor het altijd beantwoorden van de "waarom dan?"-vraag. Zonder het geduldige antwoord geven op deze vraag was ik nooit zo nieuwsgierig en kritisch geworden dat dit proefschrift er kon komen. **Jort**, heel erg bedankt voor het lezen en voor de oneindige discussies over alles en niets.

Thank you all for making it through this thesis. I'm looking forward to the future and hope to stay in touch with all of you!

## Curriculum Vitae

Lars was born on August 28<sup>th</sup>, 1995, in Stadskanaal, a ribbon village in the north-east of the Netherlands. He enjoyed his childhood there and later attended Gymnasium at the Ubbo Emmius Lyceum. Inspired by his chemistry teacher, he embarked on a journey into Life Science & Technology (LST) in 2013, a double degree bachelor program shared by Leiden University and Delft University of Technology. In 2015, he took a gap year to serve as secretary for the LST study association, studievereniging LIFE. Following a full-time board year, he undertook a minor in Science & Research Based Business. He completed his bachelor in 2017 with a research project in environmental biotechnology on fluorescent *in situ* hybridisation. Lars moved to Delft and engaged in the Biochemical Engineering master's in 2017, graduating *cum laude* in 2020 with the MSc thesis "Modelling syngas fermentation in hollow fibre membrane reactors". During this time, he also pursued a MSc on Management of Technology, with a thesis on gas fermentation in the business context. Captivated by gas fermentation, he pursued a PhD project under the guidance of Prof. Dr. Ir. Henk J. Noorman, Prof. Dr. Ir. Cristian Picioreanu and Dr. Ir. Cees Haringa, ultimately culminating into this dissertation. After completing his PhD, Lars would like to go abroad to continue working on scale-up of (gas) fermentations. Besides research, Lars finds joy in outdoor activities like long-distance (race) biking, hiking and ice-skating. He enjoys reading and discussing on a wide range of subjects, from sport and politics, to philosophy.
