## CHAPTER I

### ZEOLITES: AN INTRODUCTION

#### GENERAL OVERVIEW

The term zeolite was first mentioned in scientific literature by Cronstedt (see opposite page) in 1756 (1) as the name of an aluminosilicate mineral (stilbite) that seemed to steam when heated. The word zeolite was derived from the Greek words *zeo* and *lithos* meaning boiling stone. Since that time, 41 naturally occurring zeolites have been identified (2). The first ones were observed in basalts which had been altered by hydrothermal geological processes that sometimes formed crystals of museum display quality. Late in the 19th century zeolite occurrence in sedimentary tuffs and marine sediments was detected (3). Both before and after the second World War these reports became numerous, with zeolite formations often found in fairly large amounts, present in vitric tuffs, dry saline lake beds (in association with bentonites) and in low grade metamorphic rocks. For example, the city of Naples is underlain by a zeolitic deposit, some 200 km<sup>2</sup> in area, which is only five to ten thousand years old.

From the early 1940's onwards systematic synthesis studies on zeolites were started. Nowadays, thanks to successful laboratory syntheses, a large number (>200) of zeolite structures and compositions are available, most of them having no natural counterparts.

The broad present interest in zeolite science and technology has been fueled by the application of zeolite catalysts in several important oil refinery processes, resulting in an estimated annual zeolite usage of over

Figure 1. The yearly number of patents (▨, ▩) and publications (▧, ▪) regarding zeolites reported in the Chemical Abstracts. Data are averaged over the given period. Language English ▨, ▧; Language not English ▩, ▪.

35,000 tonnes as catalysts, over 45,000 tonnes in detergents and over 20,000 tonnes as adsorbents for 1987 (4).

The increase in zeolite investigations and applications can be illustrated by comparing the yearly number of publications and patents pertaining to zeolites. As shown in Figure 1 the total number of publications and patents reported in the Chemical Abstracts increased from an average of about 400 per year over the period 1967-1970 to over 2000 per year over the period 1986-1988 and is still growing.

### STRUCTURE

Zeolites are a class of framework aluminosilicates (other classes include feldspars and feldspathoids) known as tectosilicates (5), which are built from corner-oxygen-sharing  $\text{SiO}_4^{4-}$  and  $\text{AlO}_4^{5-}$  tetrahedra. The individual tetrahedra are always close to regular, but the shared oxygen linkage can accommodate T-O-T angles (T stands for T-atom, meaning tetrahedrally surrounded silicon or

Figure 3. Secondary Building Units (SBU's) observed in zeolite structures.

Figure 4. The figurative construction of four different zeolite frameworks containing sodalite cages. A pair of  $TO_4$  tetrahedra sharing one vertex is linked into a single sodalite cage. In a less cluttered representation, the oxygen atoms are omitted and the cage is represented by straight lines connecting the tetrahedral units. The sodalite cage unit is found in the SOD, LTA and FAU frameworks. Structure 6, a hypothetical framework related to that of FAU, is also constructed from sodalite cages.

aluminum atom) from  $130^\circ$  to  $180^\circ$ . Figure 2 shows how  $TO_4$  tetrahedra form the basic structure of phillipsite. In contrast to high-density species as quartz or cristobalite, the aluminosilicate frameworks of zeolites exhibit high and uniform porosities.

Figure 5. Representations of selected members of the zeolite family, showing pores of various sizes, shapes and dimensionalities. The outlines of the cages and channels are drawn as straight lines connecting adjacent tetrahedral sites (see Table 1).

Zeolite structures can be formed by repeating so-called Secondary Building Units (SBU's, depicted in Figure 3). According to these SBU's zeolites can be classified into eight groups. A selected list is presented in Table 1. The  $\text{TO}_4$  tetrahedra can be combined to yield a large variety of framework structures (see Figure 4). In this way cage-, chain-, layer- and tubular-like structures can be formed.

Table 1. Selected aluminosilicate frameworks (cf. 5). The nomenclature of the pore structure and the code is that of Meier and Olson (9). The underlined integers indicate the number of tetrahedral atoms (Si or Al) that define the aperture. The subsequent numbers indicate the size of the aperture (in nm). For structures with more than one channel system <> and | indicate whether or not the channels are interconnected, respectively.

Code	Examples	SBU	Typical Pore structure

1) This framework has not been found to occur naturally.

2) Non-zeolite materials with this framework are also known.

3) No official SBU.

4) Silica-ZSM-22 (10).

In these structures the Loewenstein rule (8) is operative which means that no Al-O-Al linkages are present in the zeolite framework.

The 39 different framework topologies that have, up-to-date, been observed for aluminosilicate zeolites have pores that vary in shape, size and dimensionality as depicted in Figure 5. The naked LTA and FAU frameworks (for code and explanation see Table 1), for example, have large cages, 1.14 and 1.18 nm in diameter, which are interconnected through smaller constrictions or windows of 0.41 and 0.74 nm in crystallographic diameter, respectively. The naked CAN, LTL, MAZ and TON frameworks have one-dimensional channels with diameters of 0.62, 0.71, 0.74 and 0.47 nm, respectively. The framework of ZSM-5 (MFI) has two orthogonal interconnected elliptical channel systems with diameters about 0.55 nm (cf. Table 1). Schematic representations of some three-dimensional zeolite channel patterns are depicted in Figure 6.

Figure 6. Formal representation of channel patterns in a) sodalite hydrate, b) zeolite A, c) zeolite RHO, d) faujasite, e) ZSM-5 and f) ZSM-11.

## CHEMICAL COMPOSITION

It is preferable to define a zeolite by its framework topology because its chemical composition may vary greatly. A general formula for the aluminosilicate zeolites can be written as

The presence of units with an overall formula of  $AlO_2^-$  in the framework provides the zeolite with a negative charge which is compensated by m-valent cations M. These nonframework cations are, at least in hydrated materials, usually mobile and can generally be replaced by a range of mono-, di- or trivalent cations through ion exchange in an appropriate solution under mild conditions.

Threedimensional frameworks based on linked  $(Al, Si)O_4$  tetrahedra can cover the Si/Al range from 0 up to infinite. A convenient but arbitrary subdivision of phases in this range has been given by Barrer (3) and is listed in Table 2. Some specific or typical Si/Al ratios of zeolites are presented in Table 1. Table 3 shows the influence of the Si/Al ratio, which ranges from 1 to infinity, on some physical properties of zeolites.

Table 2. 3-dimensional frameworks based only on tetrahedra (aluminate, aluminosilicate, silica). Table was taken from reference 3.

Class	Si/Al ratio (x)	Examples
1	$0 < x < 1$	Aluminate sodalites; bicchulite
2	$1 < x < 5$	Feldspars (non-porous), feldspathoids (porous and non-porous), zeolites (porous)
3	$5 < x < 12$	Zeolites (ferrierite, svetlozarite; porous)
4	$x \geq 12$	Zeolites (porous)
5	$x = \infty$	Crystalline silica's (porous and non-porous)

synthesis of small cage-containing structures as sodalite or gmelinite but also resulted in the preparation of new siliceous materials as N-A, ZK-4 and alpha. These zeolites are structural alike to zeolite A (LTA), but with a much higher silica to alumina ratio than that of zeolite A made in a solely NaOH-containing system (17).

Exploration of a range of tetraalkylammonium compounds as templating agents resulted, using the tetraethylammonium cation, in the synthesis of zeolite beta, the first high silica zeolite ( $\text{Si/Al} > 20$ ) (18), which structure was elucidated recently (19). Shortly thereafter, a number of high silica zeolites, i.e. ZSM-5 (20), ZSM-8 (21) and ZSM-11 (22) were reported in patent publications applying template reagents as tetrapropyl-, tetraethyl- and tetrabutylammonium compounds respectively, in the synthesis mixture. These developments led in 1977 to the synthesis of Silicalite-1 (structural isomorphous to ZSM-5) by Flanigen et al. (23) which was the first 'zeolite' having an infinite Si/Al ratio. This success led to another class of crystalline porous silica's including Silicalite-2 (ZSM-11 structure, (24)), TEA-silicalite (25), Al-free ferrierite (26) and silica-ZSM-22 (TON framework, (10)). These crystalline porous silica's are named molecular sieves as the name zeolite is restricted to compositions in which both Si and Al appear as the framework metal ions.

It seems that the presence of suitable organic species as template in molecular sieve synthesis supports the crystallization and stabilization of a particular structure. The exact role of these molecules is as yet not fully understood (17) as templates can be either locked up or be desorbable. Thus during synthesis two template-to-structure situations can be distinguished. First, zeolite cages occupied by template; for example, the tetramethylammonium which fits and is locked into sodalite cages containing frameworks or intersecting channels occupied by template, as exemplified by the presence of tetrapropylammonium cations in ZSM-5 (12,27) situated at

Figure 7. The geometry of the tetrapropylammonium ions in zeolite ZSM-5. Space filled drawings looking into the straight (left) and sinusoidal (right) channels of the zeolite.

channel crossings as depicted in Figure 7. Secondly desorbable templates might be present, as for instance triethylenetetramine (TETA) in the synthesis of the channel zeolite Nu-10 (Chapter IV). The template trapped within the voids of the zeolite product must be removed before the zeolite can be effectively used as a sorbent or catalyst. This is achieved by calcination in air or oxygen at temperatures between 400 and 600°C to degrade the template and burn any 'deposited' carbon (28). Alternatively an oxygen plasma technique may be used at lower temperature (29).

The importance of templates in zeolite synthesis is underlined by the large amount of literature published on this subject (i.e. references 3, 17, 30-32, see also Chapter IV, Table 2 (33)) occasionally leading to the crystallization of new zeolites. As an example we mention the synthesis of Sigma-1 by Stewart and Johnson (32) using 1-aminoadamantane as the template molecule.

## CATION EXCHANGE

As mentioned earlier mobile, non-framework cations like  $\text{Na}^{\text{I}}$  are present in the as synthesized classical zeolites to compensate the negative  $\text{AlO}_2^-$  species. In 1850 Way (34) and Thompson (35) clarified the nature of ion exchange in soils which led to investigations on zeolites from 1870 onwards (36). The cation-exchange process occurs when ions from solution replace counterions within the crystal structure. The effective cation-exchange percentage of a zeolite when subjected to a certain ion is not only influenced by the concentration of the competing ions in solution and in the zeolite itself, but also by the inherent selectivity of that zeolite for the cations under consideration. The total cation-exchange capacity of a zeolite is often difficult to measure because certain cation positions sometimes require enhanced temperatures to replace the cation from these locations. Therefore by convention, cation selectivity is always measured relative to the ion being released by the zeolite. In the cation exchange process between a zeolite particle and an aqueous solution cations move from the bulk solution to a zeolite dependant stagnant waterlayer which surrounds the zeolite particle. After diffusion through this film the cations often have to dehydrate partly in order to enter the zeolites pores and channels. The exchange process itself is usually very rapid with the restriction made above. Concomitantly other cations are released from the zeolite to the solution (37).

---

A detailed description on this subject has been published by Nieuwenhuizen et al. (38). These authors show that  $\text{Mg}^{\text{II}}$  ion exchange in zeolite NaA is 300 times slower than  $\text{Ca}^{\text{II}}$  ion exchange at  $32^\circ\text{C}$  and  $\text{pH}=9$ . As both divalent ions, in the hydrated form, are too large to enter the zeolite partial disruption of the hydration sphere of the cation has to take place. Since the activation energy of dehydration of  $\text{Ca}^{\text{II}}$  is lower than that of the smaller  $\text{Mg}^{\text{II}}$ ,  $\text{Ca}^{\text{II}}$  ion exchange will be faster as dehydration is the rate limiting

step. The leaving  $\text{Na}^{\text{I}}$  ion will diffuse faster than the incoming divalent ions. The Ca-exchange properties of NaA are applied in the detergent industry where NaA nowadays plays an important role in detergent compositions as phosphate substitute (39).

Besides modification of the accessibility of the zeolites (see paragraph Adsorption, (40)), cation exchange in zeolites can also lead to the incorporation of catalytically active species in the zeolite (41) to be discussed later in this Chapter. Finally cation exchange sometimes increases the zeolite's stability (42).

### ADSORPTION

Following quantitative measurements of water vapour  $\longleftrightarrow$  zeolite equilibria by Tamman (43), Grandjean (44) made some notable early studies on the sorption of heavy vapours as  $\text{I}_2$ ,  $\text{Br}_2$ ,  $\text{Cl}_2$  and  $\text{Hg}$  in chabazite in 1910. McBain (45) introduced the term 'molecular sieve' to describe the selectivity of some micro-porous carbons and zeolites in the uptake of molecules according to size. Molecules too large to enter the micropores were sorbed much less than smaller ones which could enter.

Figure 8. 8-, 10- and 12-membered rings of oxygen, showing the maximum pores of some zeolites.

Figure 9. Chart showing a correlation between the pore size of some zeolites together with the critical diameter of various molecules.

Based on their adsorption properties, zeolites can be classified as small pore, medium pore or large pore. In general, these classifications have been related to the presence of 8-, 10- and 12-membered rings respectively, in the oxygen sub-lattices, determining the maximum accessibility as shown in Figure 8. Recent structural data on high silica zeolites (i.e. ZSM-5 (27), ZSM-22 (10), ZSM-23 (46) and ZSM-48 (47)) indicate a variety of pores and shapes (circular, elliptical etc.) within the classifications. Thus, subtle differences in the adsorption of various molecules may result from small differences in shape. The accessibility of several zeolites is presented in Figure 9 along with some typical molecular dimensions.

The recent discovery of the 18-ring aluminophosphate molecular sieve VPI-5 (see paragraph on isomorphous substitution) by Davis et al. (48) can be seen as an important breakthrough that will restimulate the search for new large pore molecular sieves, previously only covered by

pillared clays. The VPI-5 molecular sieve seems to be structurally closely related to the MCM-9 SAPO molecular sieve patented (49) but not recognized as superlarge pore zeolite.

The actual pore size of a zeolite sometimes depends on the type of cation present. Type A zeolites have a cubic structure with pore windows just big enough to allow normal paraffins and other linear organic molecules to pass. Monovalent cations (e.g. sodium, potassium) in zeolite A occupy -amongst other sites- positions in the 8-membered ring and therefore reduce the actual pore size to below 0.4 nm. Divalent cations, however, require only 50% of the cationic sites of monovalent cations and leave enough 8-membered rings free to allow normal paraffins to diffuse through. Isoparaffins and other branched alkanes are more

Figure 10. a) Some molecular diameters. b) Schematic illustration of the entry of octane into a 8-ring pore and blockage of an iso-octane hydrocarbon at a channel aperture in a zeolite.

bulky than normal alkanes and therefore cannot enter CaA (see Figure 10). An important industrial process (Isosieve; Union Carbide) regarding the separation of branched and linear hydrocarbons is based on this ability of zeolite CaA.

Another shape-selective adsorption is the separation of p-isomers from mixtures of disubstituted benzenes by means of zeolites as ZSM-5 and Nu-10. Some data on the adsorption of organic molecules into these zeolites are presented in Table 4. A comparison of the adsorption data for ZSM-5, Silicalite-1 and Nu-10 reveals that the intracrystalline pore volume of Nu-10 is smaller than that of ZSM-5 and Silicalite-1 which cannot only be accounted for by the absence of channel intersections in the intracrystalline pore structure of Nu-10 (52) but is to be ascribed to the slightly smaller pore diameter of Nu-10 as well (see Table 1). Table 4 shows furthermore that competitive adsorption of xylenes, from the liquid phase, into ZSM-5 results in a high p-selectivity.

At higher temperatures the pores enlarge slightly and the kinetic energy and molecular vibrations of the diffusing molecules overcome repulsion forces at pore entrances allowing molecules to wiggle through somewhat narrower pores than expected on the basis of X-Ray dimensions whereafter (catalytic) conversion is possible (54). However, not only

Table 4. Intracrystalline sorption capacity of ZSM-5 (49), Silicalite-1 (50) and Nu-10 (51) for different sorbates for single adsorption on outgassed samples by low sorbate pressures (upper half) and competitive adsorption (52) for a mixture containing 0.5 g o-xylene, 0.5 g m-xylene and 0.5 g p-xylene in 2 ml 1,3,5-triisopropylbenzene (lower half).

Adsorbent (Si/Al ratio)	Adsorption Temp. (K)	Amount of material adsorbed (mg/g)				
		o- xylene	m- xylene	p- xylene	ben- zene	n- hexane
Silicalite-1 ( $\infty$ )	298	54.1	73.1	112.4	110.8	122.1
H-ZSM-5 (38)	303	93.3	94.3	127.2	104.5	117.0
H-Nu-10 (60)	296	6.6	13.7	41.8	30.7	52.5
H-ZSM-5 (49)	283	0.1	0.0	67.0		
H-ZSM-5 (49)	298	2.2	2.4	61.0		
H-ZSM-5 (49)	313	2.2	6.0	58.0		

the pore size determines the adsorption characteristics. The Si/Al ratio is an important factor as well (see Table 3) amongst others because it is related to the amount of cations present. A zeolite as CaA (Si/Al=1) highly prefers water whereas Silicalite-1 (Si/Al= $\infty$ ) prefers organics over water.

### ISOMORPHOUS SUBSTITUTION

Until 1982, the scope for the incorporation of framework cations other than silicon and aluminum into the zeolite was believed to be rather limited. Nowadays such limitations have been largely dispelled by the discoveries of new families of molecular sieves. Important examples towards the preparation of molecular sieves having non-aluminosilicate frameworks include aluminophosphates discovered by Flanigen et al. ( $Al^{III};P^V=1$ ) (55), iron<sup>III</sup>-silicates (56) and boronsilicates (57). These aluminophosphates led to the development of known as well as of unknown lattice structures (cf. 48,49,55) whereas the iron- and boronsilicates have an analogon in the families of aluminosilicate zeolites.

A further expansion is isomorphous substitution in aluminophosphate (AlPO) materials. Partial substitution of aluminum and/or phosphorous by silicon leads to the so called SAPO molecular sieves (58). Apart from Si various other metal ions (as Co, Mg, Mn, Zn, As, Ti) can be incorporated into the AlPO and SAPO frameworks, which then are described as MeAPO- and MeAPSO molecular sieves respectively (59-61). Therefore, a more general formula for zeolite type materials based on 4-connected networks is the following (62)

with Be, B, Al, Si, P, Ga, Ge. etc. as tetrahedral lattice atoms (T). M and M' are exchangeable and nonexchangeable metal cations, respectively. N non-metallic cations (e.g. generally removable upon heating), (aq) chemically bonded water (or other strongly held ligands of T-atoms), and q

sorbate molecules which need not to be water. The essential part in square brackets denotes the 4-connected framework which is anionic or neutral. (OH) represents the presence of interrupted frameworks or hydroxobridges. Although only main group elements are listed among the T-atoms other possible T-atoms should not be excluded as referred to earlier.

Undoubtedly, these new molecular sieve materials (no zeolites according to the definition which is restricted to Si/Al systems), as well as zeolites themselves, are a promising and rapidly growing field of investigation and application.

### CATALYSIS

Zeolites have a number of properties which make them interesting and valuable for heterogeneous catalysis: (a) they have exchangeable cations, allowing the introduction of different cations or combinations thereof with various catalytic properties; (b) if the cationic sites are exchanged directly or indirectly to  $H^+$ , a spectrum of Bronsted acidity up to very strong acid sites can be obtained. Apart from a (c) high internal surface area ( $>600 \text{ m}^2/\text{g}$ ) they (d) have pore diameters with usually a discrete accessibility and (e) these pore diameters are in the order of molecular dimensions (63). Further, the incorporation of various (f) metal<sup>0</sup> clusters or (g) metal-complexes is possible. Because of their high thermal stability (h) regeneration/reactivation by high temperature treatment is often possible. Therefore, the interior of a zeolite can be transformed into an unique catalytic environment for chemical transformations (cf. 64).

Molecular shape-selectivity in zeolite catalysis was first reported by Weisz and Frillette (65) in 1960. In a subsequent article Weisz et al. (66) defined two basic types of shape selectivity (see Figure 11); reactant selectivity, where certain molecules are admitted into the zeolite and others excluded by virtue of their size and shape (kinetic

Figure 11. Reactant (top) and product (middle) selectivities as exemplified by the selective cracking of n-heptane and the preferred formation of p-xylene, respectively. Restricted transition state selectivity (bottom). Because of its large reaction intermediate the formation of 1,3,5 trimethylbenzene is prevented.

diameter); and product selectivity, which applies to molecules formed -in equilibrium- within the zeolite where escape from the zeolite is dictated by similar steric considerations. This general definition was later extended by Csicsery (67) who added categories of cage effects and restricted transition state selectivity (Figure 11), and by Shabtai (68) who proposed that a zeolite may constrain reactant molecules in preferred conformation and/or orientation prior to reaction.

Figure 12. Schematic representations of zeolite reactant selectivity, product selectivity and reaction selectivity.

These selectivities can be combined under the name reaction selectivity covering selectivity in parallel reactions as well as in consecutive reactions (cf. Figure 12).

Reactant selectivity occurs when part of the reactant molecules are too large to diffuse through the catalyst pores. To these molecules just the outer zeolite surface is available then. Examples of reactant selectivity include dehydration of alcohols: n-butanol dehydrates at 260°C over both CaA and CaX whereas sec-butanol and isobutanol only dehydrate over CaX (63); cracking of paraffins (69) (industrially applied in the Mobil Selectoforming process (70)); and selective hydrogenation of unsaturated organics over  $M^O$  loaded zeolites as  $Rh^ONaY$  (71) or  $Pt^OZSM-5$  (72).

Product selectivity occurs when some of the product(s) formed within the pores are too bulky to diffuse out as observed products. They are either converted to less bulky molecules (e.g. by equilibration or cracking) or eventually deactivate the catalyst by blocking the pores (Figure 11a). Product selectivity has been observed, for example in the

para-selective methylation of toluene (73) over ZSM-5 zeolites modified by the introduction of Fe, B or P species. The high para-selectivity is attributed to the relatively strong adsorption of o- and m-xylene on the acidic reaction sites. The p-isomer is more rapidly desorbed because of its difference in size, shape and polarity when compared to the m- and o-isomers. Product selectivity can also be observed in the bromination of halobenzenes (74).

In reaction selectivity certain reactions are prevented or retarded because the transition state is too large for the space available inside the molecular sieve. In the ideal case, both the reactants and the potential products are free to diffuse through the zeolite's pores, but the formation of the transition state of undesired reactions is inhibited because it is too large (cf. Figure 12). An example is the acid-catalyzed transalkylation of dialkylbenzenes (see Figure 11). In this reaction one of the alkyl groups is transferred from one molecule to another which involves a bulky diphenylmethane-type transition state. Over HY zeolite and amorphous silica-alumina symmetrical trialkylbenzenes are formed together with the other isomers, while over H-mordenite the symmetrical trialkylbenzene is almost absent from the reaction product (63). Reaction selectivity has also been observed in bromination (75), acylation (76) and oxidation reactions (77).

#### INDUSTRIAL USE

Since their introduction as a new class of commercial adsorbents in 1954, molecular sieve zeolites have grown into an estimated quarter of a billion dollar industry and have led to the creation of a new branch of chemical technology. Commercial utilization of these materials in the fields of drying, cation exchange, selective adsorption and catalysis has been developed in most areas of the chemical industry with major applications in detergents as cation exchanger, in petroleum refining and in petrochemical processing as

catalysts and adsorbents. Zeolites are widely used in the drying and purification of natural gas, cracked gas and liquid paraffins; in desulfurization processes; for the separations of normal and branched paraffins, the separations of various mixtures of aromatic organic compounds and for oxygen/nitrogen separation. Major catalytic applications are as conversion catalysts in cracking, hydrocracking, alkylation and paraffin isomerization (78).

The interest for zeolites in catalytic reactions has started in the early sixties with the observation that small quantities of zeolites incorporated in the then used petroleum cracking catalysts as silica-alumina and silicaclay materials significantly improved their catalytic properties (79). A breakthrough in this application was the use of rare earth cation exchanged zeolite X and Y because, along with its increased cracking ability, increased gasoline production at the expense of both light gas and coke could be achieved (4). The zeolites enhanced hydrogen transfer activity is an important factor here. Nowadays, the fluidized catalyst cracking application is the largest as well as the oldest application of zeolite catalysts in which dealuminated ultra-stable faujasite (US-Y) is used as the cracking catalyst promotor to enhance octane yields and as a hydrocracking catalyst (28).

The main industrial applications of zeolites are summarized in Table 5. Application of both adsorption and catalysis is found in the Shell/Union Carbide Total

---

Isomerization Process (TIP). This process is a combination of the Shell Hysomer process (Pt-mordenite:  $C_5-C_6$  isomerization) and the Union Carbide Isosieve process and results in gasolines having a highly improved research octane numbers (RON) (81).

Recently Holderich et al. (82) and van Bekkum and Kouwenhoven (83) published reviews upon the use of zeolites as a catalyst for the preparation of organic compounds, including fine chemicals.

Table 5. Main commercial processes involving zeolites (cf. 28,80).

Process	Catalyst	Products
Catalytic cracking	RE-Y, US-Y	gasoline, fuel oil
Hydrocracking	Co, Mo, W, Ni on faujasite, mordenite, eri- onite	kerosine, jet fuel benzene, toluene, xylene
Alkylation of aromatics	ZSM-5	p-xylene, ethyl- benzene, styrene
Xylene isomerization	ZSM-5	p-xylene
Dewaxing	Ni/ZSM-5 mordenite	increase in octane number
Selectoforming	Ni/erionite	LPG production
Methanol to gasoline	ZSM-5	gasoline with high octane number
Hydroisomerization	Pt or Pd on mordenite	i-hexane, heptane
Olefin drying	K-A	olefins
Iso/n-paraffin separation	Ca-A	pure n-paraffins, branched paraffins

Natural zeolites (having no constant composition) find industrial fields of applications without necessarily conflicting with the synthetic ones, especially when large quantities are used. World utilization of natural zeolites presently reaches 230-250,000 tons per year, resulting in a total (natural + synthetic) yearly demand of over 300,000 tonnes (4,84) of zeolitic material for catalytic as well as for non-catalytic applications. An overview on the utilization of natural zeolites for 1985 is given in Table 6. Considering the exceptionally large but obviously often impure deposits, natural zeolites are preferable over synthetic ones in utilizations requiring a massive use of zeolite material.

#### SCOPE OF THIS THESIS

In this laboratory the modification and characterization of zeolites together with their (catalytic) use in organic chemistry have been studied by Roelofsen (85), Wortel (86) and Oudejans (87) who mainly investigated the selective

Table 6. Picture of the world utilization of natural zeolites for 1985 (Approximate consumption values in ton/year). Table was taken from reference 84.

catalytic properties of zeolites in organic reactions and by van der Gaag (88) who also studied the synthesis and characterisation of the high silica zeolite ZSM-5 together with isomorphous substitution on ZSM-5 type materials.

Chapters II, III and VIII of this Thesis deal with the zeolite ZSM-5. Chapter II describes an improvement on the IR-characterization of ZSM-5 as reported by van der Gaag et al. (89). Chapter III shows that the Al-gradient present in ZSM-5 influences the rate and selectivity of its dissolution in NaOH and HF. In Chapter VIII the geometry and conformation of the tetrapropylammonium (TPA) template in zeolite ZSM-5 was compared with other TPA-containing crystal structures.

The synthesis of the relatively new high silica zeolite Theta-1/Nu-10, with Si/Al ratios in the same order of magnitude as of ZSM-5, has been described in Chapter IV. Several templates were studied and optimal synthesis conditions were determined.

A good catalytic test for this Nu-10 zeolite is the reaction of aqueous ammonia and ethanol towards pyridines (Chapter V) as reported earlier by van der Gaag (88,90,91) and Oudejans (87,90). An improved reaction scheme for this reaction together with a relatively high selectivity towards pyridines is described in Chapter VI.

Some exploratory work has been performed upon the catalytic synthesis of hydroxymandelic acid from phenol and glyoxylic acid. The dealuminating properties of glyoxylic acid in an aqueous medium led to a publication of this laboratory describing the homogeneously catalyzed formation of hydroxymandelic acid (93) and to Chapter VII in which experimental work on dealumination of zeolites by glyoxylic acid is presented.

## CHAPTER II

### THE $\sim 1030\text{ cm}^{-1}$ BAND IN IR SPECTRA OF ZEOLITE ZSM-5

#### ABSTRACT

Crystalline ZSM-5 materials, of different composition, morphology and particle size, were studied with infrared spectroscopy. A frequently observed but never assigned absorption in the  $1060\text{--}1010\text{ cm}^{-1}$  region is discussed. It is concluded that the absorption indicates non-ZSM-5 framework material in the surface layer of the particles with an average particle size larger than 2 microns.

#### INTRODUCTION

When studying ZSM-5 synthesis, IR spectroscopy can be used as a fast initial selection on the quality of the zeolite material obtained (1). Apart from the characteristic lattice vibrations of ZSM-5 an indication about purity is found by the intensity ratio of the  $550$  and the  $450\text{ cm}^{-1}$  band (2). Frequently we observed a vibration between  $1060$  and  $1010\text{ cm}^{-1}$  in IR spectra of ZSM-5 particles. Several published IR spectra of ZSM-5 also show this absorption band although no assignment is given (3-7).

To examine if this vibration can be correlated to the ZSM-5 framework or to an impurity, the effects of several parameters, such as morphology and chemical composition, on the band between  $1060$  and  $1010\text{ cm}^{-1}$  were studied.

## EXPERIMENTAL

Several preparation methods were used to obtain crystalline ZSM-5 materials of different morphologies (3,8-13). Large monocrystals (up to 400 microns in the c-direction) were grown from systems with relatively low Si and Al concentrations (14).

The samples were identified with rontgen diffraction (XRD) and characterized by IR and scanning electron microscopy (SEM). Some samples were quantitatively analyzed by X-ray fluorescence (XRF). The chemical composition of the monocrystals was determined by electron microprobe analysis (EMPA). A monocrystal structure, including the template, has been solved (15).

The mid IR spectra were recorded in the transmission mode on a Perkin Elmer 521 Grating Infrared Spectrometer using the KBr pellet technique, in such a way, that the sample was mixed well with the powdered KBr whereafter a disc was pressed. An IR spectrum of a large monocrystal (polished down to a thickness of 6 microns along the b-axis) was recorded on a Bruker IFS 85 Spectrometer, equipped with a Bruker Infrared Microscope using a diaphragm of 120 microns. The crystal was directed parallel to the b-axis. X-ray powder diffraction data were obtained with a Type II Guinier de Wolff camera, using CuK $\alpha$  radiation. SEM photographs were made on a Jeol Jxa-50A Electron Microanalyzer. The electron microprobe analysis was performed on a Jeol Superprobe 733. XRF analyses were performed on a Philips PW 1400 Rontgen Spectrometer using lithium borate glass pellets containing the disclosed sample.

## RESULTS AND DISCUSSION

SEM photographs show five different morphologies of ZSM-5: type IA. large monocrystals, type IB. apparently well grown small monocrystals but internal twinning around the a-axis

Type IA

100  $\mu$

Type IB

5  $\mu$

Type IIA

5  $\mu$

Type IIB

5  $\mu$

Type III

2  $\mu$

Figure 1. A macroscopic photograph and scanning electron micrographs of zeolite ZSM-5 showing different types of morphologies. IA. monocrystal (mounted on a glass capillary; IB. internally twinned monocrystals (here Silicalite-1); IIA. 'intergrown' crystals; IIB. 'twinned' crystals; and III. spherulites.

is not excluded (16), type IIA. 'intergrown' crystals, type IIB. 'twinning' crystals and type III. spherulites. Characteristic examples are shown in Figure 1.

The morphology types IA, IB and IIA are observed for crystals with high Si/Al ratios. These materials did not show the extra vibration in the  $1060-1010\text{ cm}^{-1}$  region. Crystalline products with lower Si/Al ratios, generally show strongly intergrown and spherulitic morphologies (types IIB, III), as reported by von Ballmoos (3). In these materials we observed unambiguously the extra  $1060-1010\text{ cm}^{-1}$  vibration.

Irrespective of morphology type, no extra vibration was found in IR spectra of ZSM-5 particles with an average diameter less than 2 microns. This holds for as synthesized particles as well as for powdered materials. It is observed that the ease of powdering is by far the highest for type III particles.

Figure 2. Effect of the synthesis temperature on the formation of the extra IR-vibration in type III ZSM-5 particles. Reactant Si/Al = 50. Preparation according to reference 9. a)  $T=118^\circ$ ; b)  $T=140^\circ$ ; c)  $T=160^\circ$ ; d)  $T=180^\circ$  and e)  $T=200^\circ\text{C}$ . Reaction time 48 hours.

Varying the synthesis time shows that the extra peak develops in intensity and decreases in wavenumber during a later stage of the synthesis. A similar effect was found when the crystallization rate was altered by temperature variation as depicted in Figure 2.

Techniques used to etch the surface of the particles (partly dissolving by heating in HF at 60°C or in refluxing 2M NaOH, described in Chapter III) brings about a decrease in intensity and an increase in wavenumber of the extra vibration, as shown in Figure 3 for the NaOH treatment, which is in harmony with the observations made during synthesis. XRF measurements on a ZSM-5 sample (type IIB) show a significant increase in Si/Al ratio after 1 hour refluxing in 2M NaOH.

Infrared spectra, recorded at room temperature, of 'twinned' crystals (type IIB), which were heated up to 1300°C still show the extra vibration while the ZSM-5

Figure 3. Effect of dissolving ZSM-5 crystallites (type IIB) in a refluxing 2M NaOH solution (as described in Chapter III) on the IR frequencies of the remaining solid. A represents the transmission around 1220  $\text{cm}^{-1}$ ; B the 1080  $\text{cm}^{-1}$  vibration; C the extra vibration and D the 890  $\text{cm}^{-1}$  vibration.

Figure 4. Infrared spectra of type IIB zeolite ZSM-5 particles. a) Original material; b) original material after powdering; c) after heating the original material to 1300°C; and d) after powdering of the heated product.

structure lattice bands at  $1220\text{ cm}^{-1}$  and  $550\text{ cm}^{-1}$  are no longer present. Powdering the heated or the original sample leads to the disappearance of the extra vibration. These spectra are depicted in Figure 4.

#### - Origin of the extra lattice vibration

A typical IR spectrum of ZSM-5 particles (type IIB, see Figure 1), containing the extra vibration, is depicted in Figure 4a. Powdering these particles (SEM shows an increase in fragments  $< 2$  microns) leads to an intensity-increase for the asymmetric T-O-T stretch vibration at about  $1090\text{ cm}^{-1}$  and to disappearance of the extra  $1060\text{--}1010\text{ cm}^{-1}$  vibration.

According to Duyckaerts (17) only particles with a diameter  $< 2$  microns show 100% transmission. Larger particles tend to reduce both the apparent intensity and the resolution of the spectrum (Christiansen effect). This means there is no correlation between particle size and absorption frequency. Using a sample thickness of 6 microns we observed no transmission between 1350 and  $1000\text{ cm}^{-1}$ . Thus the IR transmission through large particles is just partly recorded from the core of the particles, and mainly from the boundary layers, where the transmission pathway through the particle is  $< 6$  microns. It is therefore believed that the extra IR vibration between 1060 and  $1010\text{ cm}^{-1}$  is related to the outer layers of the crystals. When the average particle size becomes  $< 2$  microns, the extra peak is overruled by the intensity of the  $\sim 1090\text{ cm}^{-1}$  T-O-T asymmetric stretch vibration. This indicates heterogeneity in the ZSM-5 particles.

This idea is supported by IR transmission measurements performed on large monocrystals (type 1A) of ZSM-5 (Si/Al=270), with a homogeneous Al distribution (16). Here, the extra band is not present at all (confirmed with DRIFT).

Heterogeneities in ZSM-5 crystalline materials with comparable morphologies, are known in literature. It is mentioned that Al-rich aluminosilicate entities are incorporated into the framework only at the end of the crystallization process (18-20). In addition, ESCA studies of the surface chemistry of zeolites (21) show that ZSM-5 exhibits an extensive surface presence of both alumina and sodium aluminate impurities. The presence of an Al-gradient is supported by our observations done during synthesis. The observed decrease in wavenumber of the extra vibration might indicate a change in Si/Al ratio of the outer rim of larger particles, which strongly affects the T-O-T asymmetric stretch vibration (22,23). The absence of the extra peak after extensive powdering indicates that the total amount of impurities present is less than 5 wt% (IR determination range).

Experiments to investigate the cause of the extra vibration revealed no information on defined materials. Besides the  $1060\text{--}1010\text{ cm}^{-1}$  absorption, there are found no significant other extra vibrations in the ZSM-5 IR spectra. Also the 550/450 intensity ratio reveals no information on extra material. XRD measurements show no additional diffraction patterns as well.

A heat treatment experiment shows a higher thermal stability for the cause of the extra IR vibration at about  $1030\text{ cm}^{-1}$ , with respect to the 1220 and  $550\text{ cm}^{-1}$  ZSM-5 framework vibration bands. This would indicate that the extra IR absorption is caused by non-ZSM-5 framework material.

#### ACKNOWLEDGEMENTS

The author would like to thank Mr. J.F. van Lent for the XRD analyses and Mr. D.P. Nelemans (both of the Laboratory of Metallurgy) for the SEM micrographs. Mr. Th. W. Verkroost (Department of Mining Engineering) is thanked for the XRF analyses.

Mr. A. Veermans of DSM, Geleen is thanked for the FT-IR measurements on the ZSM-5 monocrystals and for valuable discussions.

## CHAPTER III

### SOME BASE AND ACID DISSOLUTION EXPERIMENTS WITH MFI-ZEOLITES

#### ABSTRACT

The dissolution process of ZSM-5 and Silicalite-1 in 2M sodium hydroxide has been followed by scanning electron microscopy (SEM) and Si/Al analysis. It is shown that the Al gradient present in ZSM-5 influences the rate and selectivity of the dissolution of the zeolite particles. Experiments on ZSM-5 and Silicalite-1 with 1.0M hydrofluoric acid reveal a more homogeneous mechanism to be effective.

#### INTRODUCTION

In Chapter II the presence of an extra IR vibration between 1070 and 1010  $\text{cm}^{-1}$  in IR spectra of zeolite ZSM-5 particles is discussed, which is assigned to non-ZSM-5 framework material (1). The existence of heterogeneities in ZSM-5 materials is known in literature (2-5). Von Ballmoos et al. (2) describe the presence of an Al-gradient in ZSM-5. The presence of aluminum-containing non-framework material on ZSM-5 is reported by Barr et al. (5). Experiments performed in the previous Chapter indicate that the presence of an Al-gradient in ZSM-5 crystallites affects their solubility in aqueous basic media. A complete description of these experiments is given in this Chapter.

Treatment of zeolites with alkali bases is no new topic. In 1981 von Ballmoos (6) described the removal of amorphous silica-rich material, present after zeolite synthesis, by refluxing the non-calcined zeolites in a 1M NaOH solution for 1 hour. Recently Miale et al. (7) have claimed that

alkali treatment of zeolite ZSM-5 enhances the activity of the zeolite catalyst.

### EXPERIMENTAL

The preparation of the molecular sieve materials tested was based on a procedure described by Ghanami and Sand (6). Preparation of ZSM-5: molar reactant composition: 100  $\text{SiO}_2$ ; 1.7  $\text{Al}_2\text{O}_3$ ; 206  $\text{NH}_4\text{OH}$ ; 13.2 TPA-Br; 3500  $\text{H}_2\text{O}$ . Reaction conditions: teflon-lined stainless steel autoclave; no stirring during reaction;  $T=180^\circ\text{C}$ ;  $t=120$  hours.

Preparation of Silicalite-1: molar reactant composition: 100  $\text{SiO}_2$ ; 132  $\text{NH}_4\text{OH}$ ; 8.5 TPA-Br; 2076  $\text{H}_2\text{O}$ . Reaction conditions: teflon-lined stainless steel autoclave; no stirring during reaction;  $T=180^\circ\text{C}$ ;  $t=48$  hours.

Dissolution experiments with alkali base were performed as follows: As-synthesized, tetrapropylammonium containing, Silicalite-1 and ZSM-5 samples were refluxed in 2M NaOH (100 ml/0.5 g zeolite). In view of the blocking of the channels by the template molecules, mainly surface interactions are assumed to occur. The dissolution reaction was stopped by directly filtering off the hot suspension over a Buchner funnel and washing the residue with cold demineralized water. The residue was dried overnight at  $100^\circ\text{C}$  whereafter the weight of the sample was measured.

For comparison some experiments were performed in acidic medium (aqueous hydrogen fluoride). The procedure was: As-synthesized ZSM-5 or Silicalite-1 material was suspended in 1.0M-HF (1.0 g/100 ml) which was sufficient to dissolve 50 wt% of the zeolite material. The suspensions were kept at  $60^\circ\text{C}$  for 6 hours in closed polypropylene flasks. After cooling the flasks in ice the remaining solids were filtered off over a Buchner funnel and washed several times with demineralized water. Subsequently the samples were dried overnight at  $100^\circ\text{C}$ .

The samples obtained were subjected to SEM, IR and elemental analysis. SEM photographs were made on a Jeol Jxa 50A Electron Microanalyzer. The description of the IR

measurements was given in Chapter II. Of some samples the Si/Al ratio was determined by AAS using a Perkin Elmer 460 Atomic Absorption Spectrophotometer.

## RESULTS AND DISCUSSION

As described in Chapter II, Figures 2 and 3, an increase in wavenumber and a decrease in intensity of the extra IR lattice vibration was observed upon dissolution of ZSM-5 crystallites in NaOH, which is opposite to the observations made during synthesis. This IR-effect was also observed for aqueous HF as dissolving agent.

The solubility of silica(-alumina) depends on the amount of impurities present (9-11). For instance, aluminum(III), when present in minute amounts, not only reduces the rate of dissolution of silica, but by chemisorption on the surface of silica, also reduces the solubility of silica at equilibrium. This means that exposed intracrystalline material, having a higher Si/Al ratio, can dissolve faster than at surfaces with a lower Si/Al ratio. The influence of aluminum on the dissolution rate becomes apparent when non-calcined Silicalite-1 is treated with 2M NaOH. This (almost) Al-free ZSM-5 type molecular sieve dissolves at a rate about five times higher than the ZSM-5 particles (Si/Al=35.8) described below.

SEM photographs of ZSM-5 particles, treated with 2M NaOH (Figure 1) show an attack on the (amorphous) surface of the particles, especially where the twins cross (Figure 1, pictures 1 and 2). When the Al-rich surface partly has been dissolved the silica-rich inner part of the zeolite can be attacked. Because of its higher Si/Al ratio this inner part dissolves faster than the outer surface (Figure 1, pictures 3, 4 and 5). When all Si-rich parts have been dissolved, a part of the Al-rich crust remains, which finally slowly dissolves (Figure 1, pictures 6 and 7). It may be noted that the final material still exhibits an IR-spectrum which is characteristic for ZSM-5.

Figure 1. SEM photographs of ZSM-5 particles during refluxing in aqueous 2M NaOH. The numbers on the pictures indicate the reflux time in hours.

Figure 1 (continued).

Figure 2. A plot of the Si/Al ratio of the remaining ZSM-5 solids versus the amount of material dissolved in 2M NaOH. The measuring points represent the samples of Figure 1.

The dissolution sequence as monitored with SEM is supported by measurements of the Si/Al ratio of the remaining solid. As can be seen in Figure 2, first the Al-rich part of the zeolite is attacked resulting in an increase in Si/Al ratio. When the surface layer is sufficiently perforated the extraction of Si-rich material accounts for the decrease in Si/Al ratio.

The observed shift of the extra IR vibration towards  $1100\text{ cm}^{-1}$  together with a decrease in intensity (Chapter II) not only indicates a continuous dissolution at the surface (at a lower rate than for the Si-rich inner parts of the crystallites) but also a decrease in 'surface' Si/Al ratio due to preferential Si-dissolution.

The difference in dissolving behaviour between ZSM-5 and Silicalite-1 not only expresses itself in dissolution rate but can also be observed with SEM (Figures 1 and 3a,b). As mentioned above, ZSM-5 seems to be hollowed out. This in contrast to Silicalite-1 which shows a fast dissolution at

Figure 3. SEM photographs of Silicalite-1 and ZSM-5. a) Silicalite-1, starting material; b) Silicalite-1, treated with 2M NaOH for 45 minutes; c) Silicalite-1, treated with 1.0M HF and d) ZSM-5, treated with 0.1M HF.

the surface of the crystallite, giving it the appearance of Swiss cheese.

As shown in Figure 3c,d experiments using aqueous hydrofluoric acid show a more homogeneous dissolution behaviour for ZSM-5 as well as for Silicalite-1 which operates at or close to the crystal surface. This in contrast to the dissolution experiments with NaOH in which deeper reagent penetration and crystal decay is observed. A more close examination of the SEM photographs for HF-treated ZSM-5 (Figure 3d) and Silicalite-1 (Figure 3a,b,c), shows that different dissolution patterns are involved as well, emphasizing the role of the Al-rich crust.

#### ACKNOWLEDGEMENTS

The authors would like to thank both Mr. D.P. Nelemans and Mr. E.J.A. van Dam (both of the Laboratory of Metallurgy) for taking the SEM photographs. Mr. J.J. Tiggelman (Laboratory of Analytical Chemistry) is thanked for the performance of the AAS measurements.

## CHAPTER IV

### FACTORS AFFECTING THE SYNTHESIS OF ZEOLITE THETA-1/Nu-10

#### ABSTRACT

The crystallization of Theta-1/Nu-10 has been investigated. Among the templates studied oligo-iminoethylenes are the most suitable. The alkaline cation determines the Si/Al ratio at which crystalline material is formed. In the presence of  $\text{Na}^+$ , essentially pure Nu-10 is obtained at Si/Al ratios between 34 and 52, whereas  $\text{K}^+$  allows a Si/Al ratio between 9 and 17. The effects of variation of template concentration,  $\text{OH}^-/\text{SiO}_2$  ratio and synthesis time on the formation of pure Theta-1/Nu-10 are reported.

#### INTRODUCTION

In the years 1981-82 a series of high silica zeolites (see Table 1) were reported showing an essentially identical XRD-pattern. One of them, Nu-10, is reported to show a relatively high selectivity to p-xylene in the methylation and disproportionation of toluene and a predominant formation of olefins in methanol conversion (6,7).

The structures of Theta-1 (8-10) and of ZSM-22 (11), based on XRD-data (12), have been published. The zeolite has a

medium pore size. The framework is shown in Figure 1 and can be constructed from 5-1 secondary building units which places the zeolite in the pentasil group of zeolite structures. The system is one-dimensional with channels running parallel to the c-axis. The channel is formed by an elliptical 10-T-ring system (diameters 0.45x0.55 nm).

Several other zeolites have a related structure. For example, the proposed structure of ZSM-48 ((13) similar to EU-2, EU-11 and ZBM-30) consists of ferrierite sheets analogous to ZSM-22 with non interpenetrating linear channels of 0.53x0.56 nm. ZSM-23 ((14, 15) rontgenisomorphous with ISI-4 and KZ-1) is also closely related to ZSM-22, although subtle differences exist in the shapes of the pore openings. ZSM-22 and ZSM-23 contain 5-3 secondary building units. The resulting structure only

contains 5, 6 and 10-rings of T-atoms. On the other hand ZSM-48 contains a 5-5 secondary building unit (analogous to ZSM-5) which allows the occurrence of 4-rings in the structure. Structural differences between ZSM-22, ZSM-23 and ZSM-48 are illustrated in Figure 2.

Methods for the preparation of the zeolites mentioned in Table 1 show a large variety in synthesis conditions and templates (see Table 2). Some exploratory experiments following directions given in literature were not conclusive (Table 3) and from discussions with other research workers we learned that they were facing similar problems. Accordingly we decided to investigate the synthesis conditions more in detail in order to determine the synthesis limits and to find the compositions where maximum crystallinity is reached.

#### EXPERIMENTAL

Materials used in the syntheses are described in Table 4. Three types of autoclaves were used:

- A stainless-steel autoclave (capacity 1000 ml) equipped with a vertical stirrer (experiments in Table 3).
- A stainless-steel autoclave (capacity 120 ml), with teflon insert, rotating along its cylindrical axis in an oven (experiments in Table 3).
- Small stainless-steel autoclaves (capacity 30 ml), placed in a caroussel, as described by van der Gaag et al. (22), were used to study the crystallization behaviour.

The reaction mixtures were prepared according to the following method:

- The Al source and the  $\text{OH}^-$ -source are dissolved, as well as possible, in  $\text{H}_2\text{O}$  (suspension A).
- The template is dissolved in suspension A (suspension B).
- The silica source is dispersed in  $\text{H}_2\text{O}$  (suspension C).
- Suspension B is added directly to suspension C, and the mixture is stirred thoroughly (suspension D).
- Then the required amount of salt is mixed well with suspension D.
- Directly thereafter, the gel formed is transferred into

the reaction autoclave.

- The autoclave is heated at the temperature chosen, for the appropriate time, while stirring the synthesis gel with a teflon-coated magnetic stirrer.
- The reactions are quenched by rapid cooling of the autoclaves, and the solid products are filtered off and washed several times with hot water on a Buchner funnel.
- The products are dried overnight at 100°C.

The samples were identified with X-ray diffraction (XRD) and characterized by infrared (IR) spectroscopy. X-Ray powder diffraction data were obtained with a Type II Guinier de Wolff camera, using  $\text{CuK}\alpha$  radiation. The mid IR spectra were recorded in the transmission mode on a Perkin Elmer 521 Grating Infrared Spectrometer using the KBr pellet technique. Figure 3 shows the IR spectrum of Nu-10.

Figure 3. KBr IR-spectrum of Nu-10.

## RESULTS AND DISCUSSION

Introductory experiments following the literature produced the results presented in Table 3. Only in the experiments performed according to references 2 (example 5) and 15 satisfactory results were obtained. Experiments performed according to reference 1 (example 2) showed variable results. When using, as described, a stainless-steel autoclave (rotating in an oven) only amorphous material was obtained. However, using a modified experimental procedure (teflon insert, longer reaction time) the main product was Theta-1. This was in contrast to the experiments resulting in Nu-10 where no direct influence of the reaction vessel was found. This might indicate, for diethanolamine as the template, that the nature and/or texture of the vessel's walls play a role in the nucleation phenomena of the synthesis reaction.

As the best results in the exploratory experiments were obtained using a molar composition described by Hogan et al. (6) this formulation was used as a starting point for further experiments.

For convenience we will refer to the zeolites from Table 1 by using the name Nu-10. The crystallinity of the Nu-10 formed is relative and is based on IR and XRD measurements. The accuracy of the measurements is ~10%.

- template variation

Several compounds were tested for Nu-10 synthesis efficiency. The results are recorded in Table 5. Under the conditions given, also considering the results of Table 3, the oligo-iminoethylenes are satisfactory as templates and triethylenetetramine (TETA) seems to represent the optimum chain length. The fact that polyethyleneimine (PEI) does not work as a template may be related to the flocculation properties of cationic linear polymers (23); PEI is irreversibly absorbed onto the silica particles (at pH 5-10). It is also clear from Table 5 that the amino groups play an important role; when completely replaced by oxygen

<sup>1)</sup> 1.09 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.55 Na<sub>2</sub>O; x template; 4172 H<sub>2</sub>O; 58.34 NaCl. <sup>2)</sup> s=some; t=trace; mt=minute trace. <sup>3)</sup> See Table 4 for explanation.

groups (TEGO or TRIGO) no crystalline material was detected. On the basis of these results TETA was chosen as the template for further experiments. Several variables in the molar composition were studied except for the NaCl concentration. Aiello et al. (17) have shown that crystallization of Nu-10 is favoured by salt addition.

#### - synthesis time

The synthesis time was varied in order to study the crystallization behaviour of Nu-10 and to check the stability of the formed product in the reaction mixture. Batches were made with three molar compositions:

- I. 1.11 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.47 Na<sub>2</sub>O; 28.64 TETA; 4206 H<sub>2</sub>O; 59.90 NaCl
- II. 0.36 Fe<sub>2</sub>O<sub>3</sub>; 1.11 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.47 Na<sub>2</sub>O; 28.64 TETA; 4757 H<sub>2</sub>O; 59.90 NaCl
- III. 1.12 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.54 Na<sub>2</sub>O; 33.78 EDA; 4223 H<sub>2</sub>O; 61.01 NaCl

The results of a series of synthesis experiments at 180°C

are summarized in Figure 4 and Table 6. An induction period of about 10 hours is observed while the reaction in the case of TETA is completed after 25 hours yielding essentially pure and stable Nu-10 containing just a trace of  $\alpha$ -cristobalite. However, in the presence of ethylenediamine (EDA),  $\alpha$ -cristobalite is found as soon as Nu-10 is present in the reaction mixture. After 30 hours cocrystallization of another product is observed which is rontgenisomorphous.

<sup>1)</sup> 1.11 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.47 Na<sub>2</sub>O; 28.64 TETA; 4206 H<sub>2</sub>O; 59.90 NaCl. <sup>2)</sup> 0.36 Fe<sub>2</sub>O<sub>3</sub>; 1.11 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.47 Na<sub>2</sub>O; 28.64 TETA; 4757 H<sub>2</sub>O; 59.90 NaCl. <sup>3)</sup> 1.12 Al<sub>2</sub>O<sub>3</sub>; 100 SiO<sub>2</sub>; 2.54 Na<sub>2</sub>O; 33.78 EDA; 4220 H<sub>2</sub>O; 61.01 NaCl. <sup>4)</sup> In this table and the following tables numbers between brackets refer to an experiment number indicating the relative amount of a component in a product compared to that in the experiment no. specified. <sup>5)</sup> s=some, t=trace, mt=minute trace.

Figure 4. Synthesis of Nu-10. Crystallization curves obtained at 180°C for batch compositions containing EDA (×) and TETA (●,○), with (●) and without (○) addition of  $\text{Fe}_2\text{O}_3$ .

with SrD, a ferrierite type zeolite. This zeolitic product will be referred to as D. These results demonstrate that the stability of the products formed depends on the templates used. The presence of  $\text{Fe}_2\text{O}_3$  in the reaction mixture seems not to influence the crystallization of Nu-10 (cf. Figure 4).

#### - $\text{OH}^-$ concentration

The effect of the  $\text{OH}^-/\text{SiO}_2$  ratio was studied using the following crystallization formulation;

---

IV. 1.08  $\text{Al}_2\text{O}_3$ ; x  $\text{Na}_2\text{O}$ ; 100  $\text{SiO}_2$ ; 28.69 TETA; 2097  $\text{H}_2\text{O}$ ;  
57.85 NaCl

---

The molar amount of  $\text{Na}_2\text{O}$  varied from 1.35 to 8.88, resulting in a  $\text{OH}^-/\text{SiO}_2$  ratio of 0.027 to 0.176. The results for  $T=180^\circ\text{C}$  and  $t=68$  h are presented in Figure 5 and Table 7. It is clear that relatively pure Nu-10 can be made in the narrow range  $\text{OH}^-/\text{SiO}_2 = 0.04-0.08$ . At low  $\text{OH}^-/\text{SiO}_2$  ratios ( $<0.027$ ) mainly ZSM-5 together with some  $\alpha$ -cristobalite is formed. Also, at higher  $\text{OH}^-/\text{SiO}_2$  ratios cocrystallization

of ZSM-5 and  $\alpha$ -cristobalite is observed which is in agreement with the observations of Hogan et al. (6). At a  $\text{OH}^-/\text{SiO}_2$  ratio of 0.178 the product is mainly  $\alpha$ -cristobalite (no Nu-10 detectable with XRD) together with ZSM-5.

Figure 5. Synthesis of Nu-10. Effect of the  $\text{OH}^-/\text{SiO}_2$  ratio on the amount of Nu-10 present in the reaction products.

9.	40.64	50	Nu-10, s amorphous, t $\alpha$ -cristobalite (~8), mt ZSM-5

<sup>1)</sup> 1.08  $\text{Al}_2\text{O}_3$ ; 100  $\text{SiO}_2$ ; 2.48  $\text{Na}_2\text{O}$ ; y TETA; 4081  $\text{H}_2\text{O}$ ; 57.67 NaCl. <sup>2)</sup> s=some, t=trace, mt=minute trace.

40.64 are shown in Figure 6 and Table 8. The optimum TETA/SiO<sub>2</sub> ratio seems to range from 0.15-0.33. The amount of  $\alpha$ -cristobalite increases when the amount of amorphous material decreases (TETA/SiO<sub>2</sub><0.18) and when the amount of TETA increases (TETA/SiO<sub>2</sub>>0.32). A small trace of ZSM-5 is noticeable but no relation was found with the amount of TETA.

#### - Al<sub>2</sub>O<sub>3</sub>-concentration and cation variation

In order to study the effect of the SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> ratio on Nu-10 crystallization the following starting compositions, involving three different cations, were chosen:

VI. a Al<sub>2</sub>O<sub>3</sub>; 2.45 Na<sub>2</sub>O; 100 SiO<sub>2</sub>; 28.75 TETA; 4084 H<sub>2</sub>O;  
57.79 NaCl

VII. b Al<sub>2</sub>O<sub>3</sub>; 1.61 K<sub>2</sub>O; 100 SiO<sub>2</sub>; 29.03 TETA; 4092 H<sub>2</sub>O;  
57.50 KCl

VIII. c Al<sub>2</sub>O<sub>3</sub>; 4.25 (NH<sub>4</sub>)<sub>2</sub>O; 100 SiO<sub>2</sub>; 29.02 TETA; 4097  
H<sub>2</sub>O; 57.54 NH<sub>4</sub>Cl

a varied from 0 to 3.30, b and c from 0 to 11.7, T=180°C, t=67 h. For formulations VI and VII the results are given

Figure 7. Synthesis of Nu-10. Effect of the Si/Al ratio using Na<sup>+</sup> (x) as cation and K<sup>+</sup> (Δ) as cation.

<sup>1)</sup> b  $\text{Al}_2\text{O}_3$ ; 100  $\text{SiO}_2$ ; 1.61  $\text{K}_2\text{O}$ ; 29.03 TETA; 4092  $\text{H}_2\text{O}$ ; 57.50 KCl. <sup>2)</sup> s=some, t=trace, mt=minute trace.

in Figure 7 and Tables 9 and 10. The formulations with  $\text{NH}_4^+$  as a cation invariably yielded amorphous products (only without  $\text{Al}_2\text{O}_3$  (c=0) a trace of  $\alpha$ -cristobalite was found). Sodium and potassium cations show some remarkable differences in Nu-10 crystallization. With both cations, highly crystalline Nu-10 materials can be obtained. For  $\text{Na}^+$ , a maximum is found for Si/Al=34-52. With  $\text{K}^+$ , pure Nu-10 can be synthesized with Si/Al=8-11.5, which can be compared with the values 28-85 ( $\text{Na}^+$ ) and 12.5-250 ( $\text{K}^+$ ,  $\text{Cs}^+$ ,  $\text{Rb}^+$ ) reported by Hogan et al. (6). This difference in maxima is not  $\text{OH}^-/\text{SiO}_2$  dependent as will be shown later. Sodium and

potassium show the tendency to yield  $\alpha$ -cristobalite as a sideproduct at increasing Si/Al ratio ( $a < 0.70$ ,  $b < 2.92$ ). With  $K^+$  also the formation of ZSM-48 ( $1.11 < b < 3.16$ ) was observed. Decreasing the Si/Al ratio shows different tendencies for both cations. For  $Na^+$ , the ZSM-5 content is rapidly increasing when  $Si/Al < 35$  and pure ZSM-5 is obtained at  $Si/Al < 26.8$ . With  $K^+$  as cation cocrystallization of D occurs when  $Si/Al \approx 5.8$ . Below  $Si/Al = 6.5$  Nu-10 is still present but the amount of amorphous material increases.

The present experiments show that the crystallization of pure Nu-10, with  $Na^+$  as cation and TETA as template, is possible over a narrow range in the molar composition of the synthesis mixture. When  $K^+$  is used Nu-10 can be synthesized over a wider Al-concentration range. The conditions for Nu-10 synthesis, using  $K^+$  as the cation, have not been described in literature. Accordingly we have investigated this type of formulation in more detail. The Si/Al ratio and the  $OH^-/SiO_2$  ratio, having the largest effect upon the synthesis results, were varied. The following molar composition was used:

IX.  $x Al_2O_3$ ;  $y K_2O$ ; 100  $SiO_2$ ; 29.04 TETA; 4094  $H_2O$ ;  
57.31 KCl

$T = 180^\circ C$  and  $t = 67$  h;  $x = 0-12$  and  $y = -1.11-3.51$ . To obtain a negative value of  $y$  37% HCl was used instead of KOH. The results are presented in Figures 8 and 9. Both Figures show clearly that pure materials according to IR and XRD can be obtained when the Si/Al ratio is between 8.6 and 17.1 and the  $OH^-/SiO_2$  ratio is between 0.03 and 0.06 (24). At higher Si/Al values cocrystallization of ZSM-48 occurs, with the purity of the latter increasing with decreasing  $OH^-/SiO_2$  ratio. This is in agreement with the results of Araya and Lowe (25) who state that ZSM-48 can be prepared at high Si/Al ratios and low  $OH^-$  concentrations. At high  $OH^-/SiO_2$  ratios ZSM-5 cocrystallizes as expected from the previous results. It is also clear that, under these conditions, it is not possible to prepare an aluminum-free zeolite. As soon as  $Al_2O_3$  was absent in the synthesis mixture  $\alpha$ -cristobalite or  $\alpha$ -quartz was formed.

Figure 8. Synthesis of Nu-10 in a system containing  $K^+$  as a cation. The effect of the  $OH^-/SiO_2$  ratio and the Si/Al ratio on the product distribution. (1) Nu-10; (2) Nu-10 + amorphous; (3) amorphous; (4) Nu-10 + trace D; (5) Nu-10 + amorphous + trace ZSM-5; (6) Nu-10 + trace D + trace ZSM-5; (7) Nu-10 + trace  $\alpha$ -cristobalite; (8) Nu-10 + trace  $\alpha$ -cristobalite + trace ZSM-5; (9) ZSM-48 + trace Nu-10 + trace  $\alpha$ -cristobalite; (10)  $\alpha$ -cristobalite + trace Nu-10; (11)  $\alpha$ -cristobalite + trace ZSM-5; (12)  $\alpha$ -cristobalite; (13)  $\alpha$ -cristobalite + trace  $\alpha$ -quartz; (14)  $\alpha$ -quartz + trace  $\alpha$ -cristobalite; (15)  $\alpha$ -quartz.

### CONCLUSIONS

Crystallization of zeolites with the Nu-10/Theta-1/ZSM-22 framework asks for carefully chosen synthesis formulations. The cation has a pronounced effect on both the Si/Al ratio, at which crystallization occurs and on the nature of the byproducts formed.

### ACKNOWLEDGEMENT

The author would like to thank Mr. J.F. van Lent (Laboratory of Metallurgy) for the XRD analyses.

24. The Nu-10 samples described in this Chapter show the existence of differences between NaNu-10 and KNu-10

with respect to morphology and surface area and therefore in catalytic behaviour. In Chapter V a more detailed description is presented. A possible cause for this difference might be the Al-source used, although the presence of the cation can not be underestimated. Thus, results obtained for potassium (with AeroAl as aluminum source, Figure 7, experimental Al/Si=0.09) can not be duplicated with sodium as cation. By contrast, Hogan et al. (6) report just small differences between Na and K by using an aluminate as Al-source. Additional experiments with  $\text{AlCl}_3$  as the Al-source show that a maximum Nu-10 purity of 63% can be obtained at Al/Si=0.033 using potassium as the cation. When sodium is used as the cation no Nu-10 is observed.

## CHAPTER V

### THE REACTION OF AMMONIA AND ETHANOL OR RELATED COMPOUNDS TOWARDS PYRIDINES OVER ZEOLITE Nu-10

#### ABSTRACT

Pyridine bases are formed by the reaction of ethanol and ammonia over zeolite Nu-10 in the presence of oxygen, which is shown to play an essential role. Different proton-introduction procedures of the catalyst result in different catalytic activities and selectivities. Several other small amines and oxygenates are tested in the presence/absence of oxygen with respect to their selectivity towards pyridines. A combination of ethanol, methylamine and air and Nu-10 or ZSM-5 as the catalyst gives high selectivities towards pyridine and 4-methyl-pyridine. A high selectivity towards acetonitrile is found for Nu-10 catalysts containing iron besides aluminum.

#### INTRODUCTION

Compared to other heterocyclic systems, pyridine is relatively important for the chemical industry. This is reflected amongst others in the number of references and patents devoted to it. The chemical properties of the pyridine system can be divided into three categories (1): i. properties roughly parallel to those of the benzene system, modified in some degree by the presence of the ring nitrogen; ii. properties unusual for the benzene system; iii. properties associated with the unshared electron pair on the ring nitrogen.

Nowadays a demand is present for pyridines as intermediates in the synthesis of medicines, dietary supplements.

herbicides and other pesticides and disinfectants.

Two commercially important sources for pyridine bases are coal carbonisation by-products and synthetic cyclization reactions. Pyridine bases obtained from either of the two sources have their own fields of application. For instance, pharmaceutical industries need pyridine and methylpyridines (picolines) of a purity which can not be achieved by coal carbonisation.

The present large demand for pyridine bases has resulted in an appreciable increase in the world-production of synthetic pyridines from ca. 36000 tonnes for 1972 to 50000 tonnes in 1978 (2). At present, the total capacity for pyridines is estimated at 60000 tonnes per year (3).

Several synthetic routes towards pyridines have been described in literature (1-5) including aliphatic carbonyl compounds, pyrans and carbohydrates together with ammonia as starting compounds. Reactions of ketones and/or aldehydes with ammonia using metal-oxides such as silica-alumina as catalyst at temperatures between 300 and 500°C are usually applied commercially. The high costs of several aldehydes and their reactivity (instability) towards not-wanted byproducts induces several industries to investigate new reaction pathways. For example; alkenes, as aldehyde precursor, have been studied by Halasz et al. (6) as feedstock for the formation of pyridines. As early as the 1930's methods were described to obtain pyridine bases by reacting alcohols (except methanol) with ammonia over mixed metal-oxide catalysts (i.e. Zn:Al:Si or Cd:Al:Si) (7). Chang and Lang (8) were the first investigators to describe a successful application of zeolite ZSM-5 as a catalyst for the manufacture of pyridine bases out of aldehydes and ammonia. They claim a commercially attractive system showing almost no catalyst deactivation during operation. By combining the dehydrogenation, oligomerization and aromatization properties of the zeolite van der Gaag et al. (9,10,11) found that ethanol and ammonia, in the presence of oxygen, react towards pyridines when using the zeolite HZSM-5 as a catalyst. An optimal selectivity to pyridine

was obtained by using a HZSM-5 catalyst with Si/Al around 55 at temperatures between 325 and 375°C. Similarly the formation of 2,6-lutidine from acetone, methanol and ammonia over HZSM-5 was observed (12).

Recently in this laboratory the synthesis of the zeolite Nu-10/Theta-1/ZSM-22 was studied (13). This zeolite is a one-dimensional system with channels running parallel to the c-axis. The channels are formed by elliptical 10-T-ring systems (diameter 0.47x0.55 nm (14)) giving it a medium pore size. Like ZSM-5 (diameter 0.53x0.55 and 0.54x0.56 nm), the zeolite is placed in the pentasil group of zeolite structures because its framework can be constructed from 5-1 secondary building units. Essentially pure NaNu-10 was obtained at Si/Al ratios between 34 and 52 which is close to the optimal Si/Al ratio of HZSM-5 for the conversion of ethanol and ammonia towards pyridines. Zeolite HNu-10 is known to exhibit a relatively high selectivity towards p-xylene in the disproportion of toluene and a predominant formation of olefins in MeOH conversion similar to ZSM-5 (15,16). A major difference between p-xylene in ZSM-5 and Nu-10 is that in the former zeolite intersections are present which allow substantially larger reaction transition states than in Nu-10. On these grounds we decided to investigate the reaction of ethanol and ammonia over Nu-10 as the catalyst to compare its catalytic properties to those of ZSM-5.

Besides Nu-10 and ZSM-5 the present study includes mordenite as well for comparison. Mordenite was chosen because it belongs to the ferrierite type of materials to which Nu-10 is closely related.

Besides ethanol and ammonia as reactants several other oxygenates and small amines were tested for their pyridines-forming ability over zeolite Nu-10 and ZSM-5 at several reaction temperatures.

## EXPERIMENTAL

Materials

The Nu-10 zeolites used in this article were prepared as described earlier (13). The  $\text{NH}_4$ -ZSM-5 zeolite used was prepared according to Ghanami and Sand (17). The zeolite  $\text{NH}_4$ -Mordenite was supplied by Union Carbide.

The activation of the zeolite samples used in this study is described in Table 1. As an example the activation treatment of sample D is given here: A 1M  $\text{HNO}_3$  solution, 15 ml/g, was added to sample C. The suspension obtained was stirred for 3 hours, using a teflon coated magnetic stirrer, under reflux conditions. Thereafter the zeolite was filtered off over a Buchner filter and washed several times with water of 60°C. The zeolite was then dried at 100°C for one hour and subsequently calcined at 550°C during 16 hours, yielding sample D.

The zeolites were characterized using IR, XRD, AAS and TPD. BET surface areas were obtained using a single point method. Some Nu-10 samples underwent additional SEM and TEM characterizations.

All catalysts were dry pressed, crushed and sieved to obtain particles of 1.4-2.0 mm.

Procedure

The apparatus used in the catalytic experiments is essentially the same as described by Oudejans (18).

The catalyst (1 g) was placed in a fixed-bed continuous flow glass reactor of 8 mm internal diameter. The reactor was placed in an electronically controlled fluid bed oven. The carrier gas, either air or nitrogen, was passed through two thermostatted saturators containing the organic oxygen-reactant (OR) and a 0.5M aqueous solution of the N-reactant (NR), respectively. The desired flows of the reactants were obtained by adjusting and controlling the temperature of the saturators and the flow of carrier gas through the saturators.

The saturated gas streams were mixed and fed to the reactor at  $WHSV (OR) = 0.5/X \text{ h}^{-1}$  ( $X$ =number of C-atoms in OR). The molar composition  $NR:OR:H_2O:N_2:O_2$  of the reaction mixture was 1:3:6:73:17 and 1:3:6:90:0 for air or nitrogen as the carrier gas, respectively.

The reaction was carried out at a reaction temperature of 350°C and monitored every hour over a period of 18 hours by automatic sampling. The samples were analyzed on a Hewlett Packard 429 gas chromatograph equipped with a 3m 10% PEG on Chromosorb with FID for organic components and on a Perkin Elmer gas chromatograph equipped with a 1m PORAPAK Q column with TCD for inorganic components (i.e. CO and CO<sub>2</sub>) respectively. Peak integration was performed on a SpectraPhysics SP4270 integrator which was connected to the gas chromatographs.

After 18 hours the reactor temperature was raised to 450°C in steps of 25°C. After each temperature increase the catalyst remained on that temperature for 55 minutes to reach a steady state before analysis was performed.

## RESULTS AND DISCUSSION

### Materials

The zeolite Nu-10 samples were found to have two different morphologies as shown in Figure 1. The samples B, C and D (see Table 1) consist of small needles, length ~1 µm whereas the samples F, G and H are needles of ~20 µm in length.

The treatment of H-Mordenite with HNO<sub>3</sub> (sample M) leads to partial dealumination of the zeolite (cf. Table 1). XRD and IR show no structural damage. The occurrence of extra hydroxyl nests, as indicated by the absorption at 940 cm<sup>-1</sup> (19) in the IR spectrum of sample M shows that recrystallisation just partly occurs during calcination.

The low value of S of sample J (Table 1) compared to samples B, C and D might be caused by small deposits of Fe<sub>2</sub>O<sub>3</sub> present in the zeolite channels. Because of its

Figure 1. SEM-photographs of a) NaNu-10 and b) KNu-10 samples. The presence of a small amount of ZSM-5 in the KNu-10 sample (indicated by XRD) is supported by SEM.

one-dimensional structure the sorption capacities of Nu-10 can be strongly influenced by small deposits of materials leading to differences in rate and capacity of adsorption (20).

<sup>2)</sup> Despite the low bulk Si/Al ratio, TEM measurements show that the needles (see Figure 1b) are pure Nu-10 with a Si/Al ratio between 40 and 50. Apart from this amorphous Al-rich material (neither XRD nor IR-detectable and not visible in Figure 1b) is present. <sup>3)</sup> Si/Fe ratio.

## Reactions

The results of reactions of ethanol and ammonia over several Nu-10 catalysts (samples B-J) at 350°C are presented in Table 2. All NaNu-10 derived HNu-10 samples turned out to be active catalysts for the formation of pyridine. The data for samples B, C and D show that different ion exchange procedures can lead to different results. Sample C differs from samples B and D in giving a lower conversion and pyridine selectivity. Probably treatment with HCl at room temperature (sample C) gives some aluminum extraction from the T-sites in the zeolite. Because of the low ion exchange

temperature almost no Al is extracted from the pore system, leaving some alumina type species in the channels. A difference in catalytic sites ( $\gamma$ -peak) is also shown in the TPD spectra of samples B and C (Figure 2). Acidic exchange under reflux conditions (preparation sample D) removes eventually formed dealumination products from the zeolite, leaving the channels open, resulting in a catalytic activity slightly exceeding that of sample B, and a TPD spectrum similar to sample B.

Figure 2. TPD spectra of the samples B, C, D, F, G, H, J, K, L and M.

The product mixture obtained with sample J (lower pyridin. higher ethanal selectivity) is comparable with sample C. Again small particles ( $\text{Fe}_2\text{O}_3$ ) present in the channels might prevent pyridine-formation. The relatively high selectivity to acetonitrile might be due to the oxidative properties of iron oxide.

Oxygen plays an important role in the formation of ethanal, ethylamine, acetonitrile and pyridine as can be seen from the experiments with nitrogen as a carrier gas (on

samples B, F and J). Although no appreciable changes in conversion were found, a large change in selectivity is observed. Mainly diethyl ether and ethene are formed.

In all the KNU-10 derived HNU-10 samples (F-H) quite a low pyridine-forming ability was found in the reactions studied. Although not as good as samples B and D, just sample H is capable of making pyridines. A major difference between the samples F,G and H is the low value of S (Table 1) for samples F and G compared to sample H. Stirring during the ion-exchange procedures results in some cracking of the original needles (sample E, Figure 1b) giving an improvement in channel-accessibility. A comparison of samples F, G and H indicates that aromatic nitrogen-containing compounds are formed intrazeolitic while species as ethene, diethyl ether and ethylamine might be formed on the outer surface of the catalyst.

Table 3. The reaction of ethanol and ammonia, using air as carrier gas, over the zeolites ZSM-5 (sample K) and morde-nite (samples L and M) at 350°C:  $WHSV_{EtOH} = 0.25 \text{ h}^{-1}$ . Time on stream is averaged between 5 and 18 hours.

1) See Table 1. 2) ??-1 = not-identified compound.

The results of the reaction of ethanol + ammonia over some other zeolites are presented in Table 3. Zeolite HZSM-5 (sample K) shows a higher conversion towards pyridines than HNu-10 (Table 2, sample B). This because of its 2-dimensional framework resulting in a much lower "outer surface/inner pores" ratio.

Mordenite (samples L and M) not only shows a very low pyridine selectivity, but dealumination also shows almost no effect on catalytic activity. Because its Bronsted acid sites are somewhat stronger than those of HZSM-5 and HNu-10 (see Figure 1) the reaction is directed more towards the dehydration of ethanol. Despite the increase in S (table 1) combined with the almost identical catalytic behavior of the samples L and M, we must conclude that the  $\text{NH}_4$ -mordenite used, contains intrazeolitic aluminumoxide deposits which have probably no catalytic activity.

Some other oxygen compounds, i.e. diethyl ether and some other amines as methylamine and ethylamine were tested over HNu-10 in an effort to increase conversion and selectivities towards pyridine and to contribute to the understanding of the pyridine-formation reactions. The results of these experiments are given in Table 4.

A mixture of tetrahydrofuran (THF) and  $\text{NH}_3$  does not produce any pyridines. It is known in literature (1) however that THF can react with hydrogen cyanide in the vapor phase to produce pyridine, though good yields are not reported. Another possibility is the formation of pyrrole out of THF and  $\text{NH}_3$  (3). However Table 4 shows that with THF as reactant much deep oxidation products together with heavy aromatic compounds are found, caused by cracking - oxidation - and isomerization reactions in the zeolite.

Diethyl ether ( $\text{EtOEt}$ ) shows a very reactive behaviour when fed together with  $\text{NH}_3$  over Nu-10 in the presence of oxygen. Noticable is the selectivity towards 4-picoline. During the first hours on stream a good selectivity towards pyridines is found which rapidly decreases, probably caused by coke

As can be seen in Table 4 EtOAc or acetic acid is the precursor for acetonitrile, through acetamide or ammonium acetate, and not for pyridine. It is also shown that the step from acetic acid towards acetonitrile is not oxygen dependent. With EtOAc the conversion to pyridine seems to be caused by reaction of the EtOH formed (by hydrolysis) with NH<sub>3</sub>.

Ethanol with methylamine as N-reactant over Nu-10 shows a good conversion towards pyridine and is competitive towards the ethanol/ammonia/ZSM-5 system in selectivity. Remarkable is the formation of 4-substituted pyridines in the reactions where alkylamines are used as N-containing reactant. More than methylamine, ethylamine has a tendency towards intrazeolitic polymerisation, at least more on Nu-10 than on

ZSM-5, judged by the catalyst deactivation. Also noteworthy is the formation of numerous byproducts with ethanol and ethylamine over ZSM-5. The formation of these byproducts and the lower amount of intrazeolitic polymerisation must be due to the presence of cavities in ZSM-5 with a diameter larger than the channels of Nu-10, allowing not only the formation of heavier products but also keeping the reaction intermediates more separated from each other.

The higher conversion towards pyridines for alkylamines is presumably due to their basicity. The gas-phase basicities for ammonia, methylamine and ethylamine are reported to be 198, 209.8 and 212.5 kcal/mol respectively (21). This means that even at high temperatures, alkylamines more easily form a positive ammonium ion than ammonia and therefore react more easily with the acid sites of the zeolite resulting in a higher intrazeolitic N-concentration. Another important factor is the competitive intrazeolitic chemisorption between amines and pyridines. An experiment by Camia et al. (22) regarding ammonia and pyridine on HZSM-5 shows a nearly equivalent affinity to the protons of HZSM-5 with values of 207 and 222 kcal/mole for ammonia and pyridine respectively.

Figures 3 to 7 give data over the temperature range from 350 to 450°C. In Figure 3 the NaNu-10 based samples B, C, D and J are compared. The presence of  $\text{Fe}_2\text{O}_3$  in sample J is visible as a much steeper increase in EtOH-conversion, as can be seen in Figure 3a. The difference in change of EtOH-conversion for sample C compared to samples B and D affirms the idea that sample C possesses intrazeolitic barriers, probably some form of aluminum oxide. The best performer in making pyridine is sample D at 350°C. Remarkable however is that sample C, having a not so good conversion at 350°C, shows the best performance at 450°C.

When using K-originated Nu-10 (Figure 4) it can be seen that, for samples F and G, at higher temperatures some pyridine appears as if it has to be squeezed out of the zeolites channels, again indicating blocked channels.

Figure 3. Effect of the reaction temperature on the reaction of ethanol, ammonia and air towards pyridines using the Nu-10-catalyst samples B, C, D and J. a) conversion of EtOH; b) selectivity towards pyridines. Legends: A=sample B; B=sample C; C=sample D; D=sample J.

However for the more accessible sample H, a higher conversion towards pyridines is found at lower temperatures. This can also be seen by the conversion-behavior: when more channel-openings are present there is more conversion. There is however no visible effect in the conversion-change upon heating.

Figure 4. Effect of the reaction temperature on the reaction of ethanol, ammonia and air towards pyridines using Nu-10 (samples F, G and H) as the catalyst. a) conversion of EtOH; b) selectivity towards pyridines. Legends: A=sample H; B=sample G; C=sample F.

Mordenite (Figure 5), producing small amounts of pyridine at 350°C, does not improve its selectivity towards pyridine at higher temperatures. It shows however a very good selectivity towards ethene. A 90% selectivity for ethene at 425 and 450°C for sample M compared to 81% for sample L. The conversion of ethanol to pyridine catalyzed by ZSM-5 looks

Figure 5. Effect of the reaction temperature on the reaction of ethanol and ammonia over zeolites Nu-10 (sample D), ZSM-5 (sample K) and mordenite (samples L and M) using air as carrier gas. a) conversion of EtOH; b) selectivity towards pyridines. Legends: A=Nu-10; B=ZSM-5; C=mordenite (L); D=mordenite (M).

similar to those of Nu-10 in line with the fact that both catalysts have the same type of catalytically active sites. The difference in conversion in favour to ZSM-5 can be explained by the more open structure of ZSM-5. Only at 450°C diffusion rates are so fast that almost no difference in catalytic behaviour between Nu-10 and ZSM-5 is observed.

Figure 6. Effect of the reaction temperature on the conversion and selectivity for Nu-10 (sample B) using ethyl acetate (legend A), diethyl ether (legends B, C), ethanol (legend D), THF (legend E), ammonia (legends A,B,D,E), methylaniline (legend C) and air. a) conversion of O-containing reactants; b) selectivity towards pyridines.

From Figure 6 it becomes clear that an ethanol/ammonia mixture gives the best selectivity towards pyridines compared to ethyl acetate, diethyl ether and tetrahydrofuran. The high conversion rate of EtOEt, even at 350°C, shows the reactivity of this compound in the presence of zeolites. Alas it does not lead to a high selectivity

Figure 7. Effect of the reaction temperature on the conversion and selectivity towards pyridines for the catalysts Nu-10 (sample B, legends A,B,C) and ZSM-5 (sample K, legends D,E,F) using EtOH as O-reactant and ammonia (legends A,D), methylamine (legends B,E) or ethylamine (legends C,F) as N-reactant with air as carrier gas. a) conversion of EtOH; b) selectivity towards pyridines.

towards pyridines even when methylamine is used as N-reactant. Although not depicted, noticeable however is the increase in  $\text{CO}_2$ -formation at temperatures above  $400^\circ\text{C}$ , for ethyl acetate as organic compound (even when  $\text{N}_2$  is used as carrier gas) indicating a decarboxylation of the ethyl

acetate or subsequently producing acetic acid, the latter indicated by an increase in acetonitrile selectivity.

In Figure 7 it is shown that methylamine causes a substantial increase in the selectivity towards pyridines. At low temperatures conversion is better on ZSM-5 than on Nu-10 but at temperatures above 400°C no large differences are observed. The large difference between  $\text{MeNH}_2$  and  $\text{EtNH}_2/\text{NH}_3$  cannot be explained just by gas-phase basicity. A possible explanation is that methylamine is an intermediate in the reaction of ethanol and ammonia towards pyridines or a more efficient building block. A more detailed discussion on this subject will be given in the subsequent Chapter.

#### CONCLUSIONS

1. Just as ZSM-5, Nu-10 is a catalyst suitable for the preparation of pyridines out of ethanol and ammonia.
2. Ion-exchange methods used to prepare the Nu-10 catalyst partly determine its catalytic behaviour.
3. Preferable reaction-temperatures are between 350 and 400°C giving moderate conversions and selectivities.
4. The use of methylamine as N-containing reactant creates a system having a high selectivity for pyridines on Nu-10 as well as on ZSM-5.
5. The presence of iron in zeolite HNu-10 gives a catalyst suitable for the manufacture acetonitrile out of ethanol and ammonia.

---

#### ACKNOWLEDGEMENT

The Chemicals and Polymers Group of ICI, Wilton Middlesborough, UK is thanked for the performance of TEM-measurements on KNu-10.

## CHAPTER VI

# PYRIDINE FORMATION FROM ETHANOL AND AMMONIA OVER HIGH-SILICA ZEOLITES. MECHANISTIC CONSIDERATIONS

### ABSTRACT

A general discussion is given on acidic and radical sites present in high-silica zeolites as HNu-10 and HZSM-5, with relevance to pyridine-forming reactions. Zeolitic acid sites are shown to catalyze the dehydrogenation of ethanol together with condensation, cyclisation and aromatisation, while structural defects probably produce oxidation products as ethanal and formaldehyde which are thought to play an important role in the reaction. A  $C_1/C_2$ -reactant system is presented, showing a selectivity towards pyridines of 80%.

### INTRODUCTION

Although numerous methods have been claimed for the preparation of pyridine bases from acyclic molecules (such as carbonyl and dicarbonyl compounds, dicyanoalkanes, alkenes and alkynes), only a limited number of these procedures (notably the condensation of aldehydes with ammonia) are commercially applied. The use of crystalline aluminosilicates as catalysts in the reaction of aldehydes and ammonia towards pyridines has been reviewed by Golunski and Jackson (1). Halasz et al. (2) describe a bifunctional catalyst, based on oxides of tin, antimony and tellurium and containing acidic as well as selective oxidation surface centers for the preparation of pyridines out of propene and ammonia. Aluminosilicate catalysts, capable of converting aliphatic alcohols and ammonia into pyridines were found in this laboratory and include HZSM-5 and HNu-10 (3-6), both

belonging to the pentasil group of zeolite materials. Their catalytic activity and selectivity was found to depend amongst others on their Si/Al ratio which governs the number and strength of Bronsted acid sites.

Much research has been devoted to the conversion of carbonyl compounds towards pyridine bases (1), here relatively simple straightforward reaction schemes are believed to apply. However, this is not the case when ethanol and ammonia are reacted over high-silica zeolites to obtain pyridines. A description of possible reaction mechanisms with regard to the formation of 2,6-lutidine from a mixture of acetone, methanol and ammonia over HZSM-5 was given by van der Gaag (5).

In this Chapter some catalytic experiments are reported, which were carried out in order to unravel the reaction mechanism of the formation of pyridines out of ethanol and ammonia in the presence of oxygen over high-silica zeolites. The experiments include variations in the organic N-compounds as well as in their relative concentration in the reactant mixture. Also experiments reported in Chapter V will be taken into consideration.

A general discussion on the occurrence of acidic and radical sites in zeolites preceeds the discussion of pyridine formation from ethanol over HNu-10 and HZSM-5.

## EXPERIMENTAL

---

The preparative and catalytic testing procedures were described in Chapters IV (7) and V. For convenience, the coding of the preceding chapter is maintained. For full details on sample B as well as on the reaction conditions, see Chapter V.

## RESULTS AND DISCUSSION

General considerations

The catalytic activity of zeolites is often mainly related to their acidity, which arises from the bridging hydroxyl groups, associated with Bronsted acid sites. In contrast to Bronsted acid sites the characterisation of Lewis acid sites in zeolites is as yet difficult (8). For some time a tricoordinated aluminum species was held responsible for the formation of Lewis acid sites (9). However, X-ray studies showed no evidence for such sites (10). Upon dehydroxylation (of faujasite) an increase in the number of hexacoordinated Al atoms was found, using NMR techniques, with the remaining lattice aluminum atoms being tetracoordinated.  $^{27}\text{Al}$  MAS NMR studies also provide evidence that the Lewis acid sites are not the assumed trivalent lattice species but Al-species whose precise nature has not been identified (10).

Acidic sites

For ZSM-5 zeolites, Kulkarni et al. (11) showed the presence of three types of acid sites; weak, medium and strong, by temperature programmed desorption of ammonia. The strong acid sites originate from lattice aluminum atoms, while the weak and medium strength acid sites are due to terminal silanol groups and occluded extra lattice species of aluminum, respectively. The influence of these terminal silanol groups may not be underestimated. For instance, for silica-rich ZSM-5 a concentration of 4.9 silanol groups per unit cell, i.e. per 96 T-atoms, was observed by Dessau et al. (12). The concentration of internal silanols is shown to increase as the aluminum content decreases (13) and might be correlated, at least partly, with the charge compensation of the template molecules. A discussion concerning the presence of isolated or clustered silanol groups in ZSM-5 is going on at this moment between Dessau et al. (14) and van Hooff et al. (15). High temperature steaming however brings about structural rearrangements and a decrease in the number of silanol groups with assumed repair of the lattice (12).

Using IR-techniques, Brunner (16) however, was able to show that a bond breaking reaction in HZSM-5 by water molecules is operative, even at ambient temperatures. This reaction is not associated with Al and can be reversed at higher temperatures under evacuation. The presence of the structural defects mentioned in this paragraph is confirmed by the fact that the cation exchange capacity of ZSM-5 exceeds that calculated from the aluminum content of the tetrahedral framework (17).

Zeolite ZSM-5 is best known for its (super) strong acid sites (8,11,18). Strong Bronsted acid sites in HZSM-5 are situated at channel intersections and are associated with lattice aluminum atoms. At low aluminum content,  $\text{AlO}_4^-$  tetrahedra are far from each other, and maximum proton acidity is reached. As described by Barthomeuf (19) the acid strength of the strong acid sites is dependant on the number of Al-atoms on the next nearest neighbour (NNN) sites, the acidity being maximal when this number is zero. At higher intrazeolitic aluminum concentrations the extra aluminum atoms are to be included in the form of additional lattice aluminum species lowering the average -but enhancing the total- Bronsted acidity, or should occupy a non-framework position, corresponding to strong acid sites and Lewis acid sites, respectively.

Lago et al. (20) describe the formation of highly active catalytic sites by mild steaming of ZSM-5 with a specific activity 45-75 times greater than that of the normal sites. ~~These authors suggest the formation of Al species with just~~ a loose binding to the framework, so on its way to become extra lattice Al. Zoned aluminum distribution as observed in ZSM-5 (21,22) makes the co-existence of strong acid sites and somewhat weaker acid sites acceptable.

#### Radical sites

Steinike et al. (23) recently showed that upon mechanical treatment of quartz radical structures, by Si-O-Si bond breaking are formed and assumed these to be  $\equiv\text{Si}\cdot$  and  $\equiv\text{SiO}\cdot$  of which the former actually was detected. Under oxygen

pressure the primarily created radicals react to oxygen-containing radicals according to

Hydrogen also reacts with the radicals initially created by bond fracture to form  $\equiv\text{Si}-\text{H}$  and  $\equiv\text{Si}-\text{OH}$  structures, respectively.

Krylov (24) also describes the formation of such radical centers upon grinding of  $\text{SiO}_2$ ,  $\text{GeO}_2$  and  $\text{SnO}_2$ . Furthermore this author postulates a number of reactions concerning these radical sites, such as

It is known that  $\text{O}_2^-$  species are active species in heterogeneous catalysis. With regard to zeolites the effect of oxygen on the formation of radicals is not new. Already in 1967 Dollis and Hall (25) showed that the concentration of radicals in decationated faujasites was dependant on both the amount of oxygen available and the presence of dehydroxylated sites. Removal of  $\text{O}_2$  by evacuation overnight at  $550^\circ\text{C}$  was not possible showing oxygen to be strongly chemisorbed. Similarly Wierzchowski et al. (26) reported that adsorption of benzene on HZSM-5 gave rise to the formation of the monomeric benzene cation radical  $\text{C}_6\text{H}_6^+$  and that the presence of oxygen enhanced the ionizing properties of this zeolite acting as a strong oxidizer. The presence of intrazeolitic radicals in Silicalite-1 and HZSM-5 is further supported by results of Huizinga et al. (27) on the gas phase chlorination of benzene giving mainly rise to addition products, requiring radical intermediates.

Recently the formation of radicals in pentasil type zeolite-catalyzed reactions of olefins, aromatic compounds and dimethyl ether have been reported by Slinkin (28), Kucherov (29) and Rooney (30), respectively.

Regarding the structure of radical-forming sites no uniform descriptions are found. Kucherov and Slinkin (28,29,31) suggest a combination of a Bronsted acid site and a SiO• group to be formed as a result of the cleavage of the Si-O-Al lattice link. According to these authors the nature of the radical-forming site is in principle the same for all pentasil-type zeolites.

According to Shih (32) during calcination of ZSM-5 in either air or diluted oxygen atmosphere at 500°C or higher temperatures positive holes occur on oxygen atoms of the zeolitic silica-alumina surface. The author suggests interactions of the unpaired electrons with adsorbed ionizable organic molecules with an ionization energy less than 12.6 eV resulting in organic radical cations.

Rooney et al. (30) prove that the paramagnetic centres, described by Shih (32) and present in the zeolite ZSM-5 in tiny amounts as solid state defects, are the source of the free radicals formed.

Summarizing, 4 active sites can be present on zeolites:

- I. Strong Bronsted acid sites.
- II. Lewis acid sites.
- III. Weak acid sites / silanol groups.
- IV. Radical sites.

#### Pyridine-forming reactions in the presence of oxygen

The results of a series of experiments, performed in order to clarify the mechanism of the reaction of ethanol and ammonia towards pyridines using high-silica zeolites, are presented in Table 1. It is shown that in the absence of ammonia an ethanol/water/air gas mixture undergoes a fast reaction on HNu-10 at 350°C (Table 1, columns 1,2), with a high conversion towards ethene. Adsorption of pyridine on the catalyst prior to the reaction masks most of the strong acid sites resulting in a decrease in conversion towards ethene and an increase in ethanal (and CO<sub>2</sub>) formation. This shows that dehydration of ethanol towards ethene is performed on strong acid sites which mainly remain occupied by pyridine at 350°C. The increase in ethanal and CO<sub>2</sub> selectivity indicates the presence of oxidative sites reacting with either ethanol and/or with ethene. Silicalite-1 (Table 1, column 3), just having traces of Bronsted acid sites due to Al or Fe impurities, shows not only a lower EtOH conversion but a higher selectivity towards ethanal as well, when compared to Nu-10 or ZSM-5 (Chapter V), emphasizing the role of acidic sites in dehydration on the other hand. The low conversion towards pyridine over Silicalite-1 indicates that pyridine formation requires Bronsted sites. The relatively high selectivity of Silicalite-1 towards oxidation products as ethanal and CO<sub>2</sub> shows the presence of oxidative (radical) sites to be independent of aluminum as reported earlier (28, 29, 31, 32) and supports the oxygen radical sites idea as described for quartz (23,24). Dehydrogenation of alcohols towards their respective aldehydes over Silicalite-1 and dehydrated silica is described by Matsumura et al. (33,34). The authors not

only conclude that acid-base sites in silica do not exist, they also suggest that the catalytic activity may be correlated with the surface silanol concentration which again refers to the results reported by Dessau et al. (12,13).

Regarding the experiments described in Chapter V and Table 1, columns 1-3 the following reaction scheme can be presented:

Ethene and diethyl ether are formed by acid catalysis. As to the formation of ethanal several mechanistic pathways can be taken into consideration. For instance, the terminal O-atom in the  $\equiv\text{Si}-\text{OO}\cdot$  radical might lead to partial oxidation products, as ethylene oxide (24). The oxirane ring system of the ethylene oxide is highly strained and opens readily, especially in the presence of acids.

A proton catalyzed pinacol dehydration/rearrangement then may lead to ethanal. A similar reaction, from ethylene glycol towards ethanal over mordenite has been described by Chang and Curthays (35). Furthermore, oxidation of ethene

over metal oxides towards acetic acid has been reported (36a). However, these reactions are not likely to occur on Nu-10 or ZSM-5 while during our experiments no relation was found between an increase in ethene concentration and an increase in oxidation products.

Perhaps more likely is the oxidation of ethanol towards ethanal as described by Golodets and Ross (36b) and Rooney (30), initiated by the attack of surface radicals onto a secondary C-H yielding ethanal:

The observed fast oxidation in the reaction of diethyl ether and ammonia (Chapter V) supports the presence of surface-peroxy radicals in Nu-10 and ZSM-5, as ether structures are known to be oxidized rather easily by peroxides.

The catalytic formation of ethyl acetate from ethanol and acetic acid, in our experiments formed by the oxidation of ethanol, diethyl ether or ethanal, is described by Wang et al. (37) using metal oxides such as  $\text{Bi}_2\text{O}_3$ ,  $\text{MoO}_3$  and  $\text{Sb}_2\text{O}_4$ .

Almost all products formed from ethanol including ethanol itself are able to react with ammonia, at high temperatures using zeolite catalysis, resulting in the products presented in the above reaction overview. As shown in Chapter V acetic acid is a precursor for acetonitrile and not for pyridine.

According to literature data regarding pyridine syntheses (1-5, 38-41) aldehydes are good starting materials. Surface reactions of ethanal and ammonia on various heterogeneous catalysts are known to lead to 2- and 4-methylpyridine, roughly in a 1:1 ratio (1).

It should be noted however, that in our work on ethanol conversion mainly unsubstituted pyridine is observed whereas 2- and 4-methylpyridine are expected on the basis of a  $\text{C}_2$

building unit. Oxidation of the methyl group attached to the pyridine ring followed by decarboxylation is possible but experiments using 2-methyl-pyridine as the reactant were not convincing in this respect, showing just a very low conversion.

Results obtained using methylamine as N-containing reactant (Chapter V + this Chapter), using HNu-10 or HZSM-5 as the catalyst, suggest the participation of a  $C_1$  (or  $C_3$ ) building block. Addition of methanol to the EtOH/ $NH_3$  reaction mixture (Table 1, column 6) shows an increase in pyridine selectivity, which also supports the presence of  $C_1$ -species in the zeolite during ethanol conversion.

The formation of  $C_1$  fragments from ethanol might involve zeolite radicals converting ethanol into a radical cation followed by fragmentation. In mass spectroscopy the cleavage of the C-C bond next to the oxygen or nitrogen atom in alcohols or amines is a major fragmentation as shown by a dominant peak due to  $CH_2=OH^+$  ( $m/e=31$ ) or  $H_2C=NH_2^+$  ( $m/e=30$ ), respectively. According to McLafferty et al. (42) the following reactions might take place:

Relative abundances for  $H_2C=OH^+$ ,  $H_3CHC=OH^+$ ,  $H_2C=NH_2^+$ ,  $H_3CHC=NH_2^+$  are 15, 100, 100, 10 for collision activated composition (CAD) and 100, 35, 100, 20 for electron impact mass spectroscopy (EI), respectively. These values show the relatively high stability for the  $H_2C=NH_2^+$  fragment compared

to the  $\text{C}_2$  fragments. C-C scission by very strong acid sites as described by Barthomeuf (19) is not likely to occur because of the large occupation of acidic sites by ammonia and pyridines.

When investigating higher reaction temperatures, several observations can be made (Figure 1). High methylamine concentrations prevent a 100% conversion of ethanol at 450°C when compared to ammonia (Figure 1a), indicating a higher basicity of methylamine and therefore a larger occupation of acidic sites at these temperatures. Comparing the  $\text{MeNH}_2$ :EtOH ratios of 2:3 and 3:3 (Figure 1b, Figure 2) almost no difference in selectivity towards pyridines and conversion is found, indicating a maximal conversion towards pyridines at these ratios, for the Nu-10 used in our experiments.

Taking this all into account it is likely that in the reaction of ethanol and ammonia towards pyridines the following intrazeolitic reactions might occur (see Figure

Figure 3. The pyridine forming reactions which are likely to occur during the reaction of ethanol and ammonia in the presence of air, using zeolite HNu-10 or HZSM-5 as the catalyst.

3). Ammonia which is in equilibrium with acidic sites (I) reacts with ethanal (II) whereafter a C-C cleavage, forming methylimine out of ethylimine is possible (III). In another route formaldehyde is formed by fragmentation of ionized ethanol and reacts with the zeolite-ammonium system (III).

Generally imines are fairly unstable and polymerize easily. Interactions with the Bronsted acid sites of the zeolite might prevent these polymerizations by keeping the adsorbed imines separated. The addition of a molecule of ethene to these imines is possible. However, this type of propagation will not be discussed.

In a second step another  $C_1$  or  $C_2$  aldehyde may add to the deprotonated imine, followed by dehydration (IV-VI). The bismethyleneimine formed in VI is unlikely to occur under these reaction conditions and shall not be discussed. The intermediate IV is very reactive and is able to react with an aldehyde on the C of its C=N group (43) as well as on the C of its C=C group (VII, VIII, respectively). Ring closure and aromatization then leads to 2- and 4-methyl-pyridine, respectively. Similarly intermediate V can react with another  $C_2$  or  $C_1$  aldehyde.

When methylamine is used instead of  $NH_3$  the results bear mechanistically a resemblance to those obtained with the EtOH/ $NH_3$  system. However the  $C_1$ -fragment is already present from the beginning of the reaction, intermediate V might be involved, explaining the high selectivity towards pyridine and 4-methylpyridine, especially at larger  $MeNH_2$ :EtOH ratios.

For a mixture of ethylamine and EtOH with Nu-10 as the catalyst reaction products, similar to those observed using  $NH_3$ , are obtained as expected (confirm Chapter V). The presence of products as 2-methyl-5-ethylpyridine and 2,6-dimethylpyridine, when ZSM-5 is used, not only supports alkylation via the C=N group (intermediate VII) but also supports the existence of a very fast C-C scission for ethylamine resulting in a high pyridine selectivity. The absence of these products in Nu-10 catalysis can be

explained by the fact that Nu-10, with its parallel channel lattice, lacks the presence of channel crossings, restricting the size of the intermediates (transition state selectivity).

The pyridine-forming reactions result in pyridines adsorbed in the zeolite. An experiment by Camia et al. (43) regarding competitive chemisorption of  $\text{NH}_3$  and pyridine on ZSM-5 shows the heat of adsorption of ammonia and pyridine onto the Bronsted sites of the ZSM-5-catalyst to be 207 and 222 kcal/mole, respectively.

Increasing the ammonia or methylamine concentration in the feed shifts the equilibrium to the right leading to higher conversions towards pyridines as depicted in Table 1, columns 4,5,7-9 and Figure 2. Especially the increase in 4-picoline selectivity and the decrease in  $\text{CO}_2$  formation are noticeable. As can be seen in Figure 2, at 350°C the zeolite reaches maximum selectivity of almost 80% towards pyridines at a methylamine:ethanol ratio of 3:3.

The high conversions gained using alkylamines might at least partly be due to their basicity (45). Alkylamines more easily remove a pyridine from the zeolite's acid sites than ammonia, shifting reaction presented above further to the right.

The existence of such an ammonia/pyridine equilibrium in HNu-10 is shown in Figure 4 which gives  $\text{NH}_3$ -TPD curves of various samples. In Figure 4a-a 'standard'  $\text{NH}_3$ -TPD spectrum is depicted (code ABCDEF) showing the well known peaks for physisorption, medium and strong acid sites. When heating a HNu-10 sample, used for a  $\text{EtOH} + \text{NH}_3$  reaction, without any further modifications (code F) two desorption peaks are found. A small one around 120°C and a larger one around 600°C. The latter can be attributed to pyridines (46). Upon passing ammonia over the 'used' catalyst (code DEF), at room temperature, an increase in the area of the physisorption peak is observed together with a

Figure 4. Several TPD spectra of zeolite HNu-10 (sample B) used for a reaction of EtOH + NH<sub>3</sub> towards pyridines. The lettercodes provided show the order of treatment for the relevant sample. Explanation of the letters: A=calcination under air; 550°C; 1 night. B=heating to 700°C; 20°/min; under N<sub>2</sub>. C=cooling down to room temp.; under N<sub>2</sub>. D=NH<sub>3</sub>-adsorption at room temp; 30 min. E=desorption excess NH<sub>3</sub> at room temp; under N<sub>2</sub>. F=heating to 640°C; 10°/min; under N<sub>2</sub>. G=heating to 360°C; 20°/min; under N<sub>2</sub>. H=NH<sub>3</sub>-adsorption at 360°C; 20 min. I=cooling down to room temp; under NH<sub>3</sub>. K, L and M are similar to F, C and E but air is used instead of N<sub>2</sub>.

minor change in the peak around 600°C. indicating almost no exchange of pyridine for NH<sub>3</sub> at the acid sites. However upon passing ammonia over the 'used' catalyst at 360°C (code GHIDEF) a substantial decrease in the area of the high-temperature peak together with a broadening of this peak is found, indicating the existence of an ammonia/pyridine equilibrium on HNu-10 under these conditions.

The NH<sub>3</sub>-TPD spectrum of a 'used' HNu-10 catalyst (Figure 4a, code BCDEF) shows a decrease in desorption peaks

corresponding to the coverage of Lewis as well as Bronsted acid sites indicating 'coke' products, when compared to the  $\text{NH}_3$ -TPD spectrum of a calcined HNu-10 sample (code ABCDEF). Using air instead of nitrogen as a carrier gas the intrazeolitic role of oxygen is emphasized once more; the spectrum of a 'used' catalyst heated in air (Figure 4b, code K) shows the consumption of oxygen between 300 and 600°C causing negative TPD peaks. Passing ammonia over this 'calcined' catalyst (codes KLDKM and KLDMKDEF) shows the regeneration of both Lewis and Bronsted acid sites. No explanation was found for the occurrence of the shoulders around 530°C for the spectra coded K and KLDMK.

### CONCLUSIONS

The reaction mechanism for the reaction of ethanol and ammonia towards pyridines over the high silica zeolites HZSM-5 and HNu-10, proposed in this Chapter, is supported by the experimental results, although further investigations are necessary. The strong acid sites on zeolites like mordenite, X or Y prevent the release of pyridines resulting in almost no catalytic activity towards these compounds (3,6).

The role of oxygen, in the reaction of EtOH and  $\text{NH}_3$  towards pyridines, is not only the production of aldehydes, necessary to complete the reaction, but also to restore the radical sites and to 'de-coke' the zeolite, in order to keep the reactive sites accessible.

## CHAPTER VII

### AN EXPLORATORY STUDY OF THE HYDROXYALKYLATION OF PHENOL WITH GLYOXYLIC ACID OVER VARIOUS Al-CONTAINING CATALYSTS.

#### GLYOXYLATE AS A NEW Al-EXTRACTING AGENT

#### ABSTRACT

The hydroxyalkylation of phenol with glyoxylic acid over various Al-containing catalysts in aqueous medium has been studied. The catalytic activity of Al-containing solid materials could be traced back to dissolved  $\text{Al}^{\text{III}}$ -ions which catalyze the reaction of phenol and glyoxylic acid towards hydroxymandelic acid in a homogeneous way. Dealumination of zeolite Na-Y by aqueous glyoxylic acid has been studied. An initial 'zeolite concentration' effect on the Si-concentration in the solution followed by the establishment of an equilibrium in Si and Al concentrations was observed during the reaction. Addition of  $\text{Cu}^{\text{II}}$  or phenol to the initial solution influences the maximum Al-concentration in the extraction liquid.

#### INTRODUCTION

The alkylation of aromatic compounds was first described by Friedel and Crafts (1) while performing an experiment on the halogenation of benzene under the influence of aluminum chloride. Nowadays, reactions of the Friedel-Crafts type are associated with various acid-catalyzed alkylations and acylations of aromatic and aliphatic compounds (2).

In this Chapter the reaction of phenol and glyoxylic acid (3) towards hydroxymandelic acid will be considered. It is known in literature that phenol can react with glyoxylic acid under acidic as well as under basic conditions. Generally, acid catalyzed reactions of phenol with aldehydes

or ketones result in bisphenol-type products (see for example reference 4), which are, amongst others, good starting materials for the production of epikote resins and polycarbonate polymer materials. Both Hubacher (5) and the Nippon Synthetic Chemical Industry Co. Ltd. (6) describe the acid catalyzed reaction between phenol and glyoxylic acid, resulting in bis(4-hydroxyphenyl)acetic acid. Here, the intermediate compound 4-hydroxymandelic acid enters into a fast consecutive reaction.

In contrast to the acid-catalyzed reactions, reactions in alkaline media give 4- and 2-hydroxymandelic acid, the first compound being an intermediate in the synthesis of amoxycillin and cephalosporin type antibiotics and the latter compound being an intermediate in the synthesis of some sequestering agents.

The first preparation of 4-hydroxymandelic acid in an aqueous-alkaline environment has been reported by Riedel-de Haen (7) in 1936. A disadvantage of the reaction conducted at high pH is the sensitivity of aldehyde derivatives towards the Cannizzaro reaction (8): upon heating in water at  $\text{pH} > 7$ , glyoxylic acid reacts towards oxalic acid and glycolic acid. This side reaction can be suppressed by carrying out the reaction at room temperature but then excessive reaction times are required for the hydroxy-alkylation. However, Schouteeten and Christidis (9) describe a procedure using higher temperatures and a

relatively short reaction time at  $\text{pH} > 10$ , yielding mainly 4-hydroxymandelic acid (p/o ratio = 6).

In a search for a new and milder procedure to prepare 4- (or p-)hydroxymandelic acid, we explored the use of zeolites as a shape-selective catalyst for this reaction, considering the well known para-selectivity of medium pore zeolites for alkylation reactions of aromatics. Also the clay mineral Hydrotalcite, with basic interlayers ( $\text{CO}_3^{2-}$ ,  $\text{OH}^-$ ) has been included in this study. However, the results obtained induced us to focus our attention on the dealuminating properties of glyoxylic acid as well as on the reaction towards hydroxymandelic acid, homogeneously catalyzed by the extracted Al-ions. Both aspects, the reaction towards hydroxymandelic acid and the exploratory investigation regarding the dealumination of zeolite Na-Y are presented in this Chapter.

## EXPERIMENTAL

Catalysts: The molecular sieve materials HZSM-5 (Si/Al = 36), Silicalite-1 and HNu-10 (Si/Al = 45) were synthesized according to procedures described in Chapters III and IV. The zeolites H-Mordenite (large pore; Zeolon 100, Norton) and Na-Y (SK40, Union Carbide) were commercially available. RE-Y (Rare Earth exchanged Y) and amorphous silica-alumina cracking catalyst LA-LPV (13wt%  $\text{Al}_2\text{O}_3$ ) were obtained from AKZO Chemie, Amsterdam. H-Y was obtained by exchanging Na-Y with a 1M  $\text{NH}_4\text{NO}_3$  solution (10ml/g) at  $80^\circ\text{C}$ , followed by calcination at  $500^\circ\text{C}$ . NaCu-Y was prepared similarly using a 0.1M  $\text{CuCl}_2$  solution (10ml/g zeolite).

The clay mineral Hydrotalcite,  $[\text{Mg}_4\text{Al}_2(\text{OH})_{12}]\text{CO}_3$ , was prepared as follows (10). Two solutions were made: The first contained 0.30 mol  $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and 0.15 mol  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  in 700 ml  $\text{H}_2\text{O}$  while the other solution contained 1.13 mol  $\text{Na}_2\text{CO}_3 \cdot 0\text{H}_2\text{O}$  in 1050 ml  $\text{H}_2\text{O}$ . In a 2L beaker 300 ml  $\text{H}_2\text{O}$  was heated up to  $80^\circ\text{C}$ . By addition of a small part of the  $\text{Na}_2\text{CO}_3$  solution the pH of the solution was brought to 8. Then, under good stirring both the nitrate and carbonate solutions

were added dropwise to the solution. During the addition, which took about 1 hour, the pH as well as the temperature were kept constant. Subsequently the suspension was stirred for another 30 minutes at 80°C. The precipitate was filtered off over a Buchner funnel, washed with 2 litres of water of 80°C and dried overnight at 80°C.

Phenol alkylation: Experiments involving the preparation of hydroxymandelic acid were performed as follows: an aqueous 0.5M glyoxylic acid (Merck) solution and phenol were mixed in a 1:1 molar ratio. The Al-containing catalyst (2g/100ml) was added and the reaction mixture was stirred. For the homogeneous reactions in the presence of  $\text{Al}^{\text{III}}$  or  $\text{Mg}^{\text{II}}$  the molar ratio glyoxylic acid: $\text{M}^{\text{n+}}$  was 3:1. NaOH was added to adjust the desired pH value. Details regarding pH, reaction time and temperature are presented in Table 1. Stirring was performed during the reaction.

Dealumination reaction: A 0.20M glyoxylic acid solution, adjusted to pH=3 with NaOH, was used for all experiments. For every experiment 50 to 150 ml of this solution was placed into a water-thermostatted glass reaction vessel equipped with a reflux unit and a magnetic stirrer bar. The temperature of the reaction vessel was kept at 70°C for all dealumination reactions. An amount of Na-Y zeolite was added to the hot solution at  $t=0$ . Samples (1 to 2 ml) were taken by using a hypodermic syringe and filtered over a 0.45  $\mu\text{m}$  micropore filter (Gelman Sciences) and subsequently stored in small sample flasks in a refrigerator, awaiting further analyses.

Analyses: Determination of the hydroxyalkylation products was performed by HPLC analysis, using a Waters Associates chromatography pump M-45, differential refractometer RI 401 and a Spectraphysics SP4100 integrator. The following conditions were employed: column C18 Nucleosil RCM 100 Module; eluent  $\text{MeOH}/\text{H}_2\text{O}/\text{TFA}$  10/90/0.1 and RI detection. The metal ion concentrations in the aluminum extraction liquids were determined by AAS on a Perkin Elmer 460 Atomic Absorption Spectrophotometer.

## RESULTS AND DISCUSSION

## - Phenol hydroxyalkylation

The experimental results are summarized in Table 1. In the absence of a catalyst hydroxymandelic acids are formed at high pH values only. The zeolites with a high Si/Al-ratio ( $>10$ ) as Silicalite-1, HZSM-5, HNu-10 and with an intermediate Si/Al-ratio as H-Mordenite show almost no catalytic effect. They even seem to suppress the reaction at pH=6.0 when compared to the reaction without catalyst. The low Si/Al ( $<5$ ) materials as zeolite Y and LA-LPV as well as the clay Hydrotalcite did catalyze the hydroxyalkylation reaction but were also found to dissolve partly during the experiments. This indicated that dissolved aluminum<sup>III</sup> coordination compounds might be responsible for the formation of hydroxymandelic acid. Tests using  $\text{Al}(\text{NO}_3)_3$  as homogeneous catalyst, confirmed the extraction/reaction idea.

Meanwhile it has been ascertained by de Vos Burchart et al. (11) that the zeolites ZSM-5, Silicalite-1, Nu-10 and Mordenite are essentially unaffected by glyoxylic acid under the conditions of Table 1.

The difference in results obtained for LA-LPV at low and medium pH values (although carried out at 100°C) indicate a pH-dependence of the o/p-ratio. The dependence of the o/p ratio upon the pH as well as the use of other multivalent metal ions as homogeneous catalyst in the alkylation of phenol by glyoxylic acid (cf. Table 1 the results obtained with NaCu-Y and H-Y) were investigated subsequently in more detail by Hoefnagel et al. (12). Figure 1 illustrates the product composition vs. time of a reaction mixture containing  $\text{Ga}^{\text{III}}$  as the homogeneous catalyst at pH 5 and 100°C. Also some disubstituted products are observed. For  $\text{Al}^{\text{III}}$ ,  $\text{Cu}^{\text{II}}$  and  $\text{Zn}^{\text{II}}$  as the catalyst the influence of the pH on the o/p-ratio is depicted in Figure 2.

Table 1. Reaction conditions and results for the reaction of phenol (0.5M) and glyoxylic acid (0.5M) towards 4- and 2-hydroxymandelic acid.

Catalyst	pH	Reaction time (min)	temp (°C)	Conversion phenol (%)	o/p ratio

#### - Dealumination of zeolite Na-Y by glyoxylic acid

A literature survey on the dealumination by low molecular weight organic acids revealed the following:

Dealumination of zeolitic materials by glyoxylic acid has not been described before. By contrast the use of the somewhat related dicarboxylic system, oxalic acid, for the dealumination of zeolites has been reported in the literature (13-15). Also data can be found regarding the association constants of Al-oxalate coordination compounds. For example, Sjöberg and Oehman (16) describe the equilibria of aluminum<sup>III</sup>-oxalic acid-hydroxide systems. By means of potentiometric and  $^{27}\text{Al}$  NMR measurements these authors determined the successive formation of the complexes  $[\text{Al}(\text{oxalate})_n]^{3-2n}$  with  $n=1,2,3$ . These mononuclear

Figure 2. The influence of the pH on the hydroxyalkylation reaction of phenol (0.5M) with glyoxylic acid (0.5M) catalyzed by Zn<sup>II</sup> (x), Cu<sup>II</sup> (o) and Al<sup>III</sup> (□) (0.025M) in water, 100°C.

complexes are found to predominate. Besides the formation of the polynuclear mixed hydroxo-complexes  $\text{Al}_3(\text{OH})_3^-$  (oxalate)<sub>3</sub> and  $[\text{Al}_2(\text{OH})_2(\text{oxalate})_4]^{4-}$  were established. These authors also describe the increase in 'solubility' of clay minerals such as kaolinite when low concentrations ( $10^{-5}$  mol/l) of ligands (L) such as citric acid or oxalic acid are present. For kaolinite this increase is restricted to solutions with  $5 < \text{pH} < 9$  for oxalic acid and with  $4 < \text{pH} < 7$  for citric acid and is ascribed to the formation of  $\text{AlL}$  and  $\text{AlL}_2$  complexes.

For zeolites Basinskii et al. (13) as well as Urbanovich et al. (14) report the use of oxalic acid in the dealumination of Y-type zeolites. Basinskii et al. investigated the decrease in catalytic activity due to dealumination of NaLa-Y and NaCa-Y by oxalic acid under reflux conditions. Urbanovich et al. treated an ultrastable zeolite Na-Y with 0.05M oxalic acid to remove intrazeolitic (non-framework) Al-species, present after hydrothermal treatments at 550 and 830°C.

Another application is claimed by McVicker et al. (15) in which metal contaminations present in hydroconversion catalysts ( $\text{Al}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3\text{-SiO}_2$  or zeolite) are removed by contacting the catalyst at 0-100°C with buffered 0.0001-5M oxalate solutions (pH 3-10) without dissolving the support.

In view of the results obtained during phenol hydroxy-alkylation zeolite Na-Y (Si/Al=2.8) was selected to study the dealuminating properties of glyoxylic acid. The influence of the glass reaction vessel upon the Si and Al measurements may be neglected as judged from the following experiment. A blank reaction under standard conditions in the absence of zeolite Na-Y shows no increase in Si and Al concentration after 300 minutes.

The results of a series of dissolution/extraction experiments with different initial amounts of Na-Y are shown in Figures 3 and 4. It may be noted that complete dissolution of 1 g Na-Y into 1L of 0.2M glyoxylic acid would result in a maximum value of 4.1 mmol Al and 7.4 mmol Si (131.6 and 238.7 ppm, respectively).

As can be seen in Figures 3 and 4 both Si and Al are removed from the zeolite material. Remarkable is the large increase in Si-concentration at the start of the reaction, which bears an almost linear relation to the initial 'Na-Y concentration'. For Al the concentration in solution rises rapidly to about 370 ppm. At the end of the reaction a maximum equilibrium of 470 ppm Al seems to be established. For Si an equilibrium concentration around 200 ppm is observed, giving a maximum (Si + Al) concentration of about 670 ppm at 70°C and pH=3 after 300 minutes reaction time (which accounts for a (Si + Al):glyoxylic acid ratio of 1:12.8) showing glyoxylic acid still to be in large excess. It may also be noted that the pH of the solution does not change significantly during the reaction. At the start of the reaction the pH rises to 3.2 and at t=300 minutes a value of 3.4 is observed.

Figure 3. Si and Al concentration versus time of the 0.2M glyoxylic acid solution during dealumination of zeolite Na-Y at 70°C and pH 3. Influence of the initial amount of Na-Y. o=4.8, □=19.7, Δ=40.6 and ▽=80.0 g Na-Y/l.

Figure 4. Effect of the initial amount of Na-Y upon the Al (●,■) and Si (○,□) concentration in solution after a reaction time of 6 (●,○) and 300 (■,□) minutes. Conditions: 0.2M glyoxylic acid, pH 3, 70°C.

A comparison with similar dissolution experiments using nitric acid (Table 2) shows that nitric acid is not extracting Al from zeolite Na-Y whilst the Si-dissolution seems to be pH-dependent. For the high concentrations of Si observed in the reactions with glyoxylic acid as extractant, having an initial Na-Y concentration of 40.6 and 80.0 g/l, a possible explanation may be the presence of small amounts of amorphous silica-rich material in the Na-Y zeolite sample.

The decrease in Si concentration in solution measured at Na-Y concentrations above 20 g/l might be explained by the observed flocculation of amorphous material (presumably silica-alumina) during the extraction reaction. The Al-curves do not show such a maximum and are all similar in shape (Figures 3 and 4). De Vos Burchart et al. (11) observed no significant decrease in glyoxylic acid concentration during the reaction excluding precipitation of glyoxalate compounds. Therefore it can be assumed that a maximum Si and Al concentration is allowed in the solution. After this equilibrium has been reached extraction from Si

Table 2. Results for dissolution/extraction experiments using glyoxylic acid or nitric acid. The initial 'Na-Y concentration', the acid used, the initial pH and the reaction time are given below. Reaction temperature was 70°C.

or Al from the zeolite material causes precipitation of material of low solubility.

The relatively high phenol conversion observed when using NaCu-Y as the catalyst (cf. Table 1) might be due to homogeneous catalysis by Al<sup>III</sup> and Cu<sup>II</sup> ions and induced us to investigate the effect of Cu<sup>II</sup> present in the solution or in the zeolite upon the progress of dealumination. For this purpose an experiment was carried out in which zeolite Na-Y (21.4 g/l) was subjected to a solution containing Cu<sup>II</sup> as well as 0.2M glyoxylic acid and pH 3 initially. The initial molar Cu/Al ratio was 0.78. Figure 5 shows the results. First rapid Cu<sup>II</sup>-Na<sup>I</sup> ion exchange is observed, causing the Cu concentration to decrease below 2300 ppm. The addition of Cu<sup>II</sup> has hardly any effect on the Si-extraction when compared to the treatment of a sample having a similar Na-Y

concentration (19.7 g/l) in the absence of  $\text{Cu}^{\text{II}}$ . The amount of dissolved Al however, increases substantially in the presence of  $\text{Cu}^{\text{II}}$ . During zeolite dealumination the exchanged  $\text{Cu}^{\text{II}}$  cations return again in the solution indicating the loss of zeolitic anionic sites. The observed decrease in Cu concentration after 150 minutes might be due to newly created Cu-binding-sites in the deposited amorphous silica-alumina.

In order to study any effect of the presence of phenol in the dealumination of Na-Y by glyoxylic acid, a reaction mixture, having a Na-Y concentration of 13.5 g/l and a phenol:glyoxylic acid (0.2M) molar ratio of 3.3:1, has been examined. By comparing the amount of dissolved Si (see Figure 6) with experiments in which phenol is absent it can be concluded that the Si-extraction is not influenced by the

Figure 5. Effect of the addition of  $\text{Cu}^{\text{II}}$  (added as  $\text{CuCl}_2$ ) to the initial reaction mixture on the dealumination of Na-Y by glyoxylic acid. ●,○ = Si concentration; ■,□ = Al concentration for a Cu containing solution (●,■) having an initial Na-Y concentration of 21.4 g/l and reference solution (○,□) without  $\text{Cu}^{\text{II}}$ , with an initial Na-Y concentration of 19.7 g/l. ▼ = Cu concentration in the solution; - - - = initial Cu concentration.

addition of phenol. By contrast, an increase in Al-extraction is observed. The phenol conversion towards hydroxymandelic acid seems to be almost complete after 500 minutes. The o/p ratio of the hydroxymandelic acid formed was 8.9 and remained constant during the reaction period.

The fact that no effect on the dealumination is observed during the progress of the phenol alkylation reaction might be explained by the observations by de Vos Burchart et al. (11) that 4-hydroxymandelic acid as well as glyoxylic acid is capable of extracting Si and Al from zeolites.

Hoefnagel et al. (11) propose that metal complexes of glyoxylate are the key intermediates in the phenol hydroxy-alkylation reactions. As shown on the next page the ortho substitution is assumed to involve coordination of both organic reactants to the metal cation catalyst, explaining

Figure 6. Effect of the addition of phenol to the initial reaction mixture on the dealumination of Na-Y by glyoxylic acid. ● = Si concentration; ■ = Al concentration for the phenol containing solution; ▽ = phenol conversion; --- = maximal phenol conversion.

the high o/p ratio. Though phenol coordination is relatively weak, ionization of coordinated phenol will result in a highly active system. Cations with a high charge density are assumed to be the most effective catalyst for this reaction.

**p-substitution of phenol**

**o-substitution of phenol**

In conclusion, our experiments show the ability of glyoxylic acid to extract Al (+ Si) from zeolitic or related materials with a low Si/Al-ratio. A detailed reaction mechanism for this dealumination can not be presented at this moment. Further investigations regarding the dealumination are in progress in this laboratory (11).

#### ACKNOWLEDGEMENTS

The author would like to thank Mr. J.J. Tiggelman (Laboratory of Analytical Chemistry) for the AAS measurements. Mr. R.W. Pierik, Mr. E.J.M. Straver and Mr. A.J. Hoefnagel are thanked for the experimental assistance.

## CHAPTER VIII

# THE GEOMETRY OF TETRAPROPYLAMMONIUM IONS IN CRYSTAL LATTICES. CRYSTAL AND MOLECULAR STRUCTURE OF BIS-(TETRA-N-PROPYLAMMONIUM)-BIS( $\mu$ -2-CHLORO)-TETRACHLORO-DI-COPPER(II)

## ABSTRACT

The conformation of the tetrapropylammonium (TPA) ion in crystal lattices is reviewed. In the crystal structures examined two different TPA conformations occur regularly, both having CCNC torsion angles around 180, 60 and  $-60^\circ$ . Eclipsed conformations (CCNC torsion angles of 0, 120 and  $-120^\circ$ ) are observed exceptionally. A relation between shape and size of the anion and the conformation of TPA is proposed. When occluded in the zeolite ZSM-5 TPA exhibits an energetically unfavourable conformation which is probably due to interactions of the terminal methyl groups with those of neighbouring TPA ions.

$(N(C_3H_7)_4)_2Cu_2Cl_6$ .  $M_r=712.54$ , triclinic,  $PI$ .  $a=9.369(1)$ ,  $b=9.352(1)$ ,  $c=11.866(2)$  Å.  $\alpha=106.45(1)$ ,  $\beta=100.05(1)$ ,  $\gamma=113.30(1)^\circ$ .  $V=866$  Å<sup>3</sup>,  $Z=1$ ,  $D_x=1.37$  g/cm<sup>3</sup>,  $\lambda(MoK\alpha)=0.71069$  Å,  $\mu=1.75$  mm<sup>-1</sup>,  $F(000)=374$ ,  $T=290$  K.  $R=0.038$  for 3252 observed reflections. The structure consists of dimeric  $Cu_2Cl_6$  units. Each copper atom shows a distorted tetrahedral coordination to four chlorine atoms. Both tetrahedra are linked by sharing an edge.

## INTRODUCTION

Since the introduction of the tetrapropylammonium (TPA) ion as a template for the synthesis of zeolite ZSM-5 (1) its structure directing role is under discussion (2-4). In zeolite synthesis TPA, as well as other tetraalkylammonium ions, seems to direct the topology of the framework and to

stabilize it when formed.

The synthesis of a ZSM-5 single crystal, large enough for a single crystal X-ray structure determination, has been described by van Koningsveld et al. (5). In this article the ZSM-5 framework structure as well as the location and conformation of the TPA ions are determined accurately and compared with structural data of TPA-ZSM-5 crystal structures reported earlier (6-8).

Molecular mechanics calculations on the conformations of 4,4-dipropylheptane (tetrapropylmethane, structural isomorphous to TPA) by van de Graaf (9), show that 4,4-dipropylheptane possesses two structurally different favourable conformations. Both conformations are very close in steric energy, having a difference of only 0.24 kcal/mole.

The two essentially iso-energetic conformations can be conveniently considered by examining the six heptyl chains present in the system and by numbering the four propyl groups of 4,4-dipropylheptane clockwise 1-4.

Figure 1. The two energetically favourable conformations of 4,4-dipropylheptane as calculated by van de Graaf (9). The small circles represent H-atoms.

In conformation A (Figure 1a) two heptyl chains (1-3 and 2-4) are in an all-trans conformation, whereas in each of the other four heptyl chains (1-2, 1-4, 2-3 and 3-4) two gauche butane interactions are present. In conformation B (Figure 1b) all-trans oriented heptane chains are absent; in two heptyl chains (1-4 and 2-3) two gauche interactions are present, whereas in the other four heptyl chains one gauche orientation can be observed. Thus conformations A and B possess the same total (8) of gauche interactions.

It may be noted that conformations around  $C_2-C_3$  and  $C_4-C_5$  are always trans.

The conformations of TPA (as reported by van Koningsveld et al. (5)) in ZSM-5 deviate from the ideal conformations A and B described above. To see if the conformations as described for 4,4-dipropylheptane also exist for TPA and to find out if deviations as reported for TPA-ZSM-5 (%) occur more frequently, a literature search on TPA-containing crystal structures has been undertaken.

As this literature search revealed a possible correlation between the size of dimeric anionic compounds and the TPA-conformation, the crystal structure of the title compound has been solved because we expected it to interpolate in the series of known (dimeric) structures.

## EXPERIMENTAL

### - $(TPA)_2-Cu_2Cl_6$ preparation and structure refinement

A hot solution of 0.1M TPA-Cl in 96% ethanol was added slowly to an equimolar amount of  $CuCl_2 \cdot 2H_2O$  dissolved in 96% ethanol. Yellow-brown crystals of  $(TPA)_2-Cu_2Cl_6$  were grown by slow evaporation at room temperature. Approximate crystal size 0.15 x 0.20 x 0.25 mm. In a similar way crystals of TPA-Br and  $CuCl_2 \cdot 2H_2O$  were prepared. The latter structure was also solved by Patterson and Fourier techniques. However, this analysis will not be reported because of disorder of the Br- and Cl-atoms.

A single crystal of the title compound was measured on an Enraf Nonius CAD-4 diffractometer. Mo-K $\alpha$  radiation, monochromated by graphite, was used for the determination of the unit cell parameters as well as for measuring the reflection intensities. The cell parameters were calculated from setting angles of 25 reflections with  $15 < \theta < 19^\circ$ . Range of hkl: 0 $\rightarrow$ 12, -12 $\rightarrow$ 11,  $\pm$ 15.  $\theta_{\max} = 28^\circ$ . 4169 independent reflections were measured. 3252 reflections with  $I > 2.85\sigma(I)$  were used.  $\omega/2\theta$  scan, scan width =  $0.95 + 0.35\tan\theta$ , max. recording time 120 s.  $\sigma_{\text{count}}(I)/I < 0.02$  was requested in a scan. Three reference reflections showed a decay of 2.0%; a correction was applied. The data were not corrected for absorption.

The structure refinement was carried out using as start positions the coordinates of the TPA-Br-CuCl<sub>2</sub> compound. The structure proved to be isomorphous. A full-matrix least-squares refinement was carried out on F with anisotropic thermal parameters for all non-H atoms. The H-atoms were located from the difference Fourier map and refined with fixed isotropic thermal parameters set equal to those of the parent C-atoms. The model converged with 3252 observations and 239 variables to  $R=0.038$ ,  $wR=0.042$ ,  $w=1$ ,  $S=1.13$ ,  $(\Delta/\rho)_{\max}=0.8$  [z-value H(422)]. The final  $\Delta\rho$  is less than  $0.60 \text{ e}\cdot\text{\AA}^{-3}$  (~ at Cl(3) position). Scattering and anomalous-dispersion factors for Cu and Cl were taken from the International Tables for X-ray Crystallography (10).

All calculations were carried out on the Delft University Amdahl 470/V7B computer using programs of the XRAY72-system (11).

#### - TPA Geometry determination and definitions

To distinguish between the stable conformations as calculated by van de Graaf (9) we name the TPA ion in which two heptyl chains (1-3 and 2-4) are in an all-trans orientation, conformer A (Figure 1a) and the other conformer B (Figure 1b).

Figure 2. Definition of  $\alpha$ ,  $\beta$  and  $\gamma$  carbons in TPA. The numberings 1, 2, 3, 4 are related to the propyl chains and are used in Figure 3 and in Table 3.

The crystal structure parameters and atom coordinates for all TPA-containing compounds (except for ZSM-5 and the title compound) were obtained from the Cambridge Structural Database (12).

In refinement of the TPA-ZSM-5 structure Waser constraints were applied (5). These coordinates were used in defining the conformation of TPA.

The geometry of the TPA ions in the crystal structures described was determined by calculating the torsion angles of the  $C_{i\alpha}$ -N bonds as well as of the  $C_{i\alpha}$ - $C_{i\beta}$  bonds. The torsion angles  $\alpha$  and  $\beta$  were calculated as the dihedral angle between the planes formed by the atoms  $C_{i\alpha}$ -N- $C_{j\alpha}$  and N- $C_{i\alpha}$ - $C_{i\beta}$  for  $\alpha$ , and by the atoms  $C_{i\alpha}$ - $C_{i\beta}$ - $C_{i\gamma}$  and N- $C_{i\alpha}$ - $C_{i\beta}$  for  $\beta$  (see Figure 2). The geometry is defined by twelve  $\alpha$  and four  $\beta$  angles.

Figure 3. Newman projections of the  $C_{1\alpha}$ -N bond (a) of conformation A. (b) conformation B and of (c) an eclipsed conformation (E). The numbering is defined in Figure 2.

Figure 3 gives Newman projections of the  $C_{1\alpha}$ -N bond in conformation A (Figure 3a) of the  $C_{1\alpha}$ -N bond in conformation B (Figure 3b) and of the  $C_{1\alpha}$  bond in case of an eclipsed conformation in the  $C_{1\beta}$ - $C_{1\alpha}$ -N- $C_{3\alpha}$  fragment.

As the numbering of the propyl chains is not essential changes in  $\alpha$  can not be used directly for the distinction between conformation A and conformation B. However, for conformation A the 12  $\alpha$ -values assigned to these chains are always pairwise equal when following any heptyl chain vice versa. This does not hold for conformation B. Here in just two of the six heptyl chains (i.e. 1-4 and 2-3, cf. Figure 2) such vice versa equality of  $\alpha$ 's is encountered.

## RESULTS AND DISCUSSION

### - (TPA)<sub>2</sub>-Cu<sub>2</sub>Cl<sub>6</sub> crystal structure

The final positional parameters are reported in Table 1. Relevant bond distances and angles are listed in Table 2. Lists of anisotropic temperature factors, H-atom positions and bonds involving H-atoms are included at the end of this Chapter. For reasons of clarity the numbering of the TPA atom parameters differs from those defined in Figure 2.

Table 1. Final fractional coordinates and equivalent isotropic temperature factors ( $\text{\AA}^2$ ) for the non-hydrogen atoms with e.s.d.'s in parentheses.  $U_{eq} = (U_{11} + U_{22} + U_{33})/3$ .

1) Cu' and Cl(2') are centrosymmetrically related to Cu and Cl(2), respectively.

The structure contains a nearly symmetrical dimeric dihalogen-bridged unit as depicted in Figure 4. The Cu atom is coordinated by Cl in a distorted tetrahedron. The bridging Cu-Cl distances are 2.321(1) and 2.307(1) Å. The distances of Cu to the terminal Cl atoms are equal within experimental error (2.195(1) Å). Similar TPA-containing dimeric dihalogen-bridged units are found for example in crystal structures of  $(\text{TPA})_2\text{-Hg}_2\text{I}_6$  (13),  $(\text{TPA})_2\text{-Sb}_2\text{Cl}_8$  (14) and  $(\text{TPA})_2\text{-Cu}_2\text{I}_4$  (15).

The TPA orientation in  $(\text{TPA})_2\text{-Cu}_2\text{Cl}_6$  is clearly in the A conformation.

The N...Cl(1) and N...Cl(3) contacts, with Cl(3) on x+1, y, z are 4.588(4) and 4.892(4) Å, respectively. The difference between these distances (~0.3 Å) might explain the slight preference of Br to occupy the Cl(3) position as

<sup>1)</sup> Cu' and Cl(2') are centrosymmetrically related to Cu and Cl(2), respectively.

Figure 4. View of the molecular structure of the [TPA-Cu<sub>2</sub>Cl<sub>4</sub>]<sup>+</sup> fragment. The thermal ellipsoids correspond to the 50% probability surfaces. The H-atoms have been left out for clarity.

observed in the isomorphous  $\text{TPA-Br-CuCl}_2$  crystal (see: Experimental). In that structure the Br atoms are distributed over the Cl(1) and Cl(3) positions.

- TPA geometry

The literature search in the Cambridge Structural Database contained 45 hits. Two hits referred to TPA in Silicalite-1 (7) which was discussed earlier (5). In five other structures no TPA-coordinates were given. Four structures were not usable because of disordered TPA molecules. Torsion angles of the TPA molecules in the remaining structures (and the title compound) are listed in Table 3 together with their point symmetry and conformation.

As can be seen in Table 3 the conformations A and B, as calculated by van de Graaf (9) for tetrapropylmethane appear in TPA as well. No preference for either conformation is observed, indicating a small difference in steric energy, which is to be expected on the basis of the data for 4,4-dipropylheptane.

Except for  $(\text{TPA})_4\text{-Mo}_4\text{H}_4(\text{CO})_{12}$  the value of  $\beta$  is hardly influenced by the counterion nor by the conformation geometry (A,B) of the TPA molecule. The average value of  $\beta$  observed over all structures is  $\pm 173^\circ$ . Observed values of  $\beta$  below  $\pm 160^\circ$  are mentioned in Table 3 (footnotes).

In addition to TPA-ZSM-5 some other TPA-containing crystal structures are found to deviate from conformations A and B. In  $(\text{TPA})_2\text{-W}_2\text{Br}_9$  and in  $(\text{TPA})_2\text{-Cu}_5\text{I}_7$  eclipsed conformations (E) are present whereas in  $(\text{TPA})_2\text{-Cu}_4\text{Br}_6$  deviating  $\alpha$ -values of  $90^\circ$  are found (-).

In the two TPA orientations of ZSM-5 as presented by van Koningsveld et al. (5) orientation 1 resembles conformation B whereas orientation 2 contains an eclipsed conformation. However, these remarks should be considered with care, because of the disordering of the TPA ions: Changing propyl chain nr. 3 to its mirror-related position leads to a new set of  $\alpha$ -values which still deviate from the A and B

Table 3.  $\alpha$  torsion angles ( $^\circ$ ) for several TPA-containing cry

conformations but does not contain an eclipsed CNCC fragment.

The occurrence of non-bonded contacts between terminal methyl groups in neighbouring TPA-ions and the rigid shape of the ZSM-5 channels might explain the deviations from the ideal A,B geometry in the  $\alpha$  torsion angles of TPA in ZSM-5. However this can not be the explanation for the deviations observed for  $(\text{TPA})_2\text{-W}_2\text{Br}_9$ ,  $(\text{TPA})_2\text{-Cu}_5\text{I}_7$  and  $(\text{TPA})_2\text{-Cu}_4\text{Br}_6$  as no close anion-cation or cation-cation contacts are observed for these materials.

In some cases it looks as if the radius or length of the anion associated with TPA affects the conformation of the TPA ion. In Table 4. some sets of compounds are arranged according to increasing radius of the anion. Small anions seem to prefer conformation A and larger anions conformation B.

In  $(\text{TPA})_2\text{-Hg}_2\text{I}_6$  and  $(\text{TPA})_2\text{-W}_2\text{Br}_9$ , having the largest radius, conformations B and E are observed, respectively. The smaller radius of  $(\text{TPA})_2\text{-Cu}_2\text{Cl}_6$  is accompanied with conformation A.  $(\text{TPA})_2\text{-Sb}_2\text{Cl}_8$  and  $(\text{TPA})_2\text{-Ga}_2\text{Br}_6$ , having an intermediate anion radius, show a mixture of both conformations.

However, a reverse order is observed for polynuclear anions. Relatively short anions have TPA in a B conformation whereas in longer or polymeric anions conformation A is observed.

These observed effects ask for a closer examination, which is beyond the scope of this Thesis.

#### ACKNOWLEDGEMENTS

Use of the services and facilities of the Dutch CAOS/CAMM Center, under grant numbers SON-11-20-700 and STW-NCH-44.073, is gratefully acknowledged. Ir. J.T.M. Linders is thanked for assistance on the CAOS/CAMM system.

## SUMMARY

This Thesis deals with high-silica zeolites and their use as catalyst in organic chemistry.

In Chapter I an introduction on zeolites is given. For example, aspects as structure, chemical composition and catalysis are discussed. In addition the scope of this Thesis is presented.

In Chapter II a frequently observed but never assigned absorption in the  $1060\text{--}1010\text{ cm}^{-1}$  region of IR spectra of zeolite ZSM-5 is discussed. To examine if this vibration can be correlated to the ZSM-5 framework or to an impurity, the effects of several parameters, such as morphology, particle size and chemical composition were studied. It is concluded that the absorption indicates non-ZSM-5 framework material in the surface layer of particles with an average particle size larger than 2 microns.

Chapter III shows that the Al-gradient present in ZSM-5 influences the rate and selectivity of the dissolution of the zeolite particles in 2M sodium hydroxide. Experiments on ZSM-5 and Silicalite-1 with 1.0M hydrofluoric acid reveal a more homogeneous mechanism to be effective.

Chapter IV discusses the factors affecting the synthesis of the high-silica zeolite Theta-1/Nu-10. In the literature a large variety in synthesis conditions and templates is mentioned. Among the templates used oligo-iminoethylenes are the most suitable. The effects of variation of template concentration,  $\text{OH}^-/\text{SiO}_2$  ratio and synthesis time on the formation of pure Theta-1/Nu-10 are reported.

Chapter V deals with the reaction of ammonia and ethanol or related compounds towards pyridines using the zeolite Nu-10 as the catalyst. Different proton-introduction procedures of the catalyst result in different catalytic activities and selectivities. It is shown that a combination of ethanol, methylamine and air and Nu-10 or ZSM-5 as the catalyst gives high selectivities towards

pyridine and 4-methyl-pyridine.

In Chapter VI considerations are given regarding the pyridine-formation mechanism out of ethanol and ammonia over high-silica zeolites. Zeolitic acid sites are shown to catalyze the dehydrogenation of ethanol together with condensation, cyclisation and aromatisation, while structural defects probably are responsible for oxidation products as ethanal and formaldehyde, which are thought to play an important role in the reaction. A  $C_1/C_2$ -reactant system is presented, showing a selectivity towards pyridine of 80%.

The hydroxyalkylation of phenol with glyoxylic acid over various Al-containing catalysts in aqueous medium is presented in Chapter VII. The catalytic activity of these Al-containing solid materials could be traced back to dissolved  $Al^{III}$ -ions which catalyze the reaction in a homogeneous way. In addition, dealumination of zeolite Na-Y by aqueous glyoxylic acid has been studied. Extraction of both Si and Al from the zeolite was observed during the dealumination reaction.

In Chapter VIII the conformation of the tetrapropyl-ammonium (TPA) ion in crystal lattices is reviewed. The crystal structure of  $(TPA)_2Cu_2Cl_6$  has been solved because it interpolates in the series of studied structures. In the crystal structures examined, two different TPA conformations occur regularly, both having CCNC torsion angles of 180, 60 and  $-60^\circ$ . Eclipsed conformations are observed exceptionally. When occluded in the zeolite ZSM-5, TPA exhibits an energetically unfavourable conformation which is probably due to interactions of the terminal methyl groups with those of neighbouring TPA ions.

---

## SAMENVATTING

Dit Proefschrift behandelt zeolieten met een hoog silicagehalte en hun gebruik als katalysator in de organische chemie.

In Hoofdstuk I wordt een algemene inleiding betreffende zeolieten gegeven. Zo worden bijvoorbeeld aspecten als structuur, chemische samenstelling en katalyse nader bekeken. Aansluitend wordt de strekking van dit proefschrift besproken.

Hoofdstuk II beschrijft een vaak waargenomen (maar tot nu toe nooit verklaarde) infraroodabsorptie in het gebied tussen 1060 en 1030  $\text{cm}^{-1}$ , in spectra van ZSM-5. Om na te gaan of er een samenhang bestaat tussen deze vibratie en het ZSM-5 rooster of de aanwezigheid van een onzuiverheid, is het effect van diverse parameters zoals morfologie, deeltjesgrootte en chemische samenstelling bestudeerd. Uit het onderzoek kwam naar voren dat de absorptie duidt op de aanwezigheid van niet tot het ZSM-5 rooster behorend materiaal dat aanwezig is in de oppervlaktelaag van deeltjes groter dan 2 micron.

Hoofdstuk III laat zien dat de Al-gradient, welke aanwezig is in ZSM-5, van invloed is op zowel de snelheid als op de selectiviteit van de oplosbaarheid van zeolietdeeltjes in 2M natrium hydroxide. Experimenten met ZSM-5 en Silicaliet-1 met 1M fluorwaterstofzuur laten een meer homogeen mechanisme zien.

Hoofdstuk IV betreft een studie naar de factoren welke van invloed zijn op de synthese van de hoog-silica zeoliet Theta-1/Nu-10. In de literatuur worden veel verschillende synthesecondities en templates genoemd in de literatuur. In de door ons geteste templates blijken oligo-iminoethylenen het meest geschikt. De effecten van variatie in template concentratie,  $\text{OH}^-/\text{SiO}_2$ -verhouding en synthesetijd op de vorming van zuiver Theta-1/Nu-10 worden gerapporteerd.

Hoofdstuk V beschrijft de reactie van ammonia en ethanol

of verwante verbindingen naar pyridines, met de zeoliet Nu-10 als katalysator. Verschillende proton-introductie procedures resulteren in verschillende katalytische aktiviteiten en selektiviteiten. Een mengsel van ethanol, methylamine en lucht, met Nu-10 als katalysator, geeft hoge selektiviteiten naar pyridine en 4-methyl-pyridine.

In Hoofdstuk VI worden een aantal overwegingen gegeven betreffende het mechanisme van de pyridinevorming uit ethanol en ammonia over hoog-silica zeolieten. Aangetoond wordt dat zure plaatsen in de zeoliet de dehydrogenering van ethanol katalyseren en daarnaast condensatie, cyclisatie en aromatisering. Voor oxidatieprodukten als ethanal en formaldehyde daarentegen, waaraan een belangrijke rol in de reactie wordt toegekend, zijn waarschijnlijk defekten in de roosterstructuur verantwoordelijk. Een  $C_1/C_2$ -reactanten systeem wordt gepresenteerd met een selektiviteit naar pyridines van 80%.

De hydroxylering van fenol met glyoxylzuur, door middel van diverse Al-bevattende katalysatoren, in een waterige omgeving wordt gepresenteerd in Hoofdstuk VII. De katalytische aktiviteit van deze vaste stoffen kan worden herleid tot opgeloste  $Al^{III}$ -ionen, welke de reactie homogeen blijken te katalyseren. Daarnaast wordt de dealuminering van de zeoliet NaY met behulp van een waterige glyoxyizuuroplossing bestudeerd. Gedurende de dealumineringsreactie wordt extractie van zowel Si als Al waargenomen.

In Hoofdstuk VIII wordt een overzicht gegeven van de conformaties van het tetrapropylammonium (TPA) ion in kristalroosters. In de beschouwde structuren komen hoofdzakelijk twee verschillende TPA conformaties voor, beide met CCNC torsiehoeken van 180, 60 en -60°. Eclipsed conformaties komen slechts bij uitzondering voor. Wanneer TPA is ingesloten in de zeoliet ZSM-5 dan is de conformatie energetisch ongunstig. Deze wordt hoogstwaarschijnlijk veroorzaakt door interacties van de eindstandige methylgroepen met die van naburige TPA ionen. De kristalstructuur van  $(TPA)_2Cu_2Cl_6$  is opgelost omdat deze

goed interpoleerbaar is in de serie van bestudeerde structuren.

## DANKWOORD

Ik zal altijd met plezier terugdenken aan de periode waarin ik werkzaam ben geweest aan de TU Delft. Een fijne werkomgeving en behulpzame (ex-)collega's hebben daartoe bijgedragen. Een aantal van hen wil ik met name bedanken:

- Herman van Bekkum, voor de onnavolgbare wijze waarop hij door zijn enthousiaste begeleiding mij steeds opnieuw inspireerde.
- Fred van der Gaag, voor het leren van de basisprincipes en de daaropvolgende verhelderende discussies.
- Koos Jansen en Herman Kouwenhoven, voor het uitdiepen en in goede banen leiden van bepaalde problemen.
- Henk van Koningsveld, zonder wiens bijdrage Hoofdstuk VIII er heel anders zou hebben uitgezien.
- Erik de Vos Burchart, Patrik Voogd en Theo Maesen voor de prettige discussies en de collegialiteit.
- J.F. van Lent, voor de snelle en accurate XRD-service.
- Wim Jongeleen, voor de inzet van al zijn vakmanschap om mijn hersenschimmen in plaatjes om te zetten.
- Ernst Wurtz, die er voor zorgde dat alles bleef draaien.
- Fred Hammers en Piet Duillaart, voor het uitstekende fotowerk.
- Robbert Pierik, Jacques van Melis, Bas Schaaf en Eugene Straver, voor de prettige samenwerking en al datgene wat ik van hen heb kunnen leren.
- De koffieclub, voor de gezellige sociaal-culturele  
werkonderbreking.
- Annelies, voor de broodnodige ondersteuning die een promovendus buiten werktijd nodig heeft.
- En last but not least mijn ouders, die het mij mogelijk hebben gemaakt te worden wat ik nu ben.

## CURRICULUM VITAE

Robert Arie le Febre werd op 17 december 1956 te Leiden geboren. Na het behalen van het HAVO-diploma in 1975 en het VWO-diploma in 1977 aan de Rembrandt Scholengemeenschap te Leiden begon hij in augustus 1977 met de scheikundestudie aan de Rijksuniversiteit te Leiden.

Het kandidaatsexamen (Sla) werd in april 1981 afgelegd. De studie voor het doctoraalexamen stond onder leiding van Prof.dr. J. Reedijk (coördinatiechemie). Dr. R.A.G. de Graaff (rontgendiffractie) en Prof.dr. J. Lugtenburg (kernspinresonantiespectroscopie). Dit examen werd in januari 1984 afgelegd.

Van 1 maart 1984 tot en met 29 februari 1988 was hij als wetenschappelijk assistent in dienst van NWO (SON). Het promotieonderzoek werd uitgevoerd aan de TU Delft onder leiding van Prof.dr.ir. H. van Bekkum.

Sinds 1 januari 1989 is hij werkzaam als analytical supervisor bij ICI Resins b.v. te Waalwijk.

## PUBLICATIES UIT DIT PROEFSCHRIFT

- Hoofdstuk II (co-auteurs J.C. Jansen en H. van Bekkum)
- Hoofdstuk IV (co-auteurs H.W. Kouwenhoven en H. van Bekkum)

Nog ter publicatie aan te bieden:

- Hoofdstuk V + Hoofdstuk VI (co-auteur H. van Bekkum)
- Hoofdstuk VII (co-auteurs E. de Vos Burchart, R. Pierik, E.J.M. Straver en H. van Bekkum)
- Hoofdstuk VIII (co-auteurs H. van Koningsveld, B. van de Graaf, J.C. Jansen en H. van Bekkum)

9. Vergeleken met aanduidingen als "tetraedrisch" en "vlak-vierkant" voor twee typen vier-coördinatie, is de aanduiding "octaëdrisch" voor een bepaalde zes-omringing wat minder gelukkig.
10. Wanneer supergeleiding bij hogere temperaturen afhangt van de hoeveelheid afwijkingen en defecten in de materialen wordt het moeilijk zich verbindingen voor te stellen die bij kamertemperatuur naast chemisch stabiel ook nog supergeleidend blijken te zijn.  
*W. Hively, American Scientist 1988, 76, 13.*
11. De bona fide aanwezigheid van olie onder een raffinaderij (Rotterdam Charlois) en van mineraalwater onder een limonadefabriek (Bunnik) toont de burger dat het ook anders kan.
12. Het schrijven van een proefschrift is te vergelijken met een zwangerschap. Na een paar maanden kun je het fatsoenshalve niet meer onderbreken.
13. De inhoud van de tenminste zes, aan het proefschrift toegevoegde, niet op het promotieonderwerp betrekking hebbende, wetenschappelijk verantwoorde en verdedigbare stellingen hangt in sterke mate af van de interpretatie van de term "wetenschappelijk verantwoord".  
*Promotiereglement TU Delft, p. 7.*
14. Het verdient aanbeveling een milieuheffing in te voeren op diervoeders, gerelateerd aan de hoeveelheid en samenstelling van de te verwachten ontlasting.
15. The proposition that the first systems which were able to evolve through natural selection were crystals of clay, leaves a muddy taste.  
*A.G. Cairns-Smith, Scientific American 1985, 252, 74.*

R.A. le Febre  
Delft, 23 maart 1989

## STELLINGEN

1. In hun studie betreffende de adsorptie en diffusie van glucose en fructose in zeoliet X verzuimen Ching en Ruthven aandacht te schenken aan de mutarotatie-isomeren van deze verbindingen.  
*C.B. Ching en D.M. Ruthven. Zeolites 1988, 8, 68.*
2. De afwezigheid van structuurkarakteristieke absorptiebanden in het IR-spectrum van zeoliet ZSM-39 als gegeven door Jansen et al. kan wijzen op een onvolledig verlopen synthesesreactie.  
*J.C. Jansen et al. Zeolites 1984, 4, 369.*
3. De extra IR-absorptie bij  $590\text{ cm}^{-1}$ , in het door Jacobs en Martens gepubliceerde IR-spectrum van zeoliet ZSM-22, duidt op de aanwezigheid van een verontreiniging.  
*P.A. Jacobs en J.A. Martens, "Synthesis of high-silica aluminosilicate zeolites", Stud. Surf. Sci. Catal. 33, Elsevier Amsterdam 1987, p. 41.*
4. Het onderzoek van Sulikowsky et al. aan aluminering van Silicaliet-1 vs. dealuminering van ZSM-5 zou aan waarde gewonnen hebben indien behalve de katalytische activiteit van gedealumineerd ZSM-5 ook die van gealumineerde Silicaliet-1 gemeten was en vergeleken met een standaard ZSM-monster.  
*B. Sulikowsky et al. J. Chem. Soc., Chem. Commun. 1987, 1542.*
5. In hun studie betreffende het effect van additieven als chloorazijnzuur op de isomeer distributie in de vloeistoffase-chlorering van benzeenderivaten over zeoliet KL als katalysator hebben Yazawa et al. verzuimd de reactie ook uit te voeren met additief in afwezigheid van zeoliet.  
*N. Yazawa, et al. "Preprints of the poster papers of the 7th Int. Zeolite Conf.", Kodansha Ltd., Tokyo 1986, p. 285.*
6. De claim van McVicker et al. dat metaalverontreinigingen in diverse katalysatoren, als alumina, silica-alumina of zeolieten, selectief verwijderd kunnen worden met behulp van oxaalzuur zonder oplossen van het dragermateriaal is aan twijfel onderhevig.  
*G.B. McVicker et al. US 4522928 (1983): DF 3337619 (1984). Dit Proefschrift. Hoofdstuk VII.*
7. De uitkomst van een zeoliet-synthese is vaak niet alleen afhankelijk van de molaire samenstelling van het reactiemengsel, maar ook van de soort en structuur van de reactanten.  
*Dit Proefschrift. Hoofdstuk IV.*
8. Het synthetiseren van moleculaire zeven met een basisch rooster blijft, hoe zuur 't ook klinkt, voorlopig een utopie.
