Tutorial on seismic interferometry: Part 1 — Basic principles and applications

Kees Wapenaar¹, Deyan Draganov¹, Roel Snieder², Xander Campman³, and Arie Verdel³

ABSTRACT

Seismic interferometry involves the crosscorrelation of responses at different receivers to obtain the Green’s function between these receivers. For the simple situation of an impulsive plane wave propagating along the x-axis, the crosscorrelation of the responses at two receivers along the x-axis gives the Green’s function of the direct wave between these receivers. When the source function of the plane wave is a transient (as in exploration seismology) or a noise signal (as in passive seismology), then the crosscorrelation gives the Green’s function, convolved with the autocorrelation of the source function. Direct-wave interferometry also holds for 2D and 3D situations, assuming the receivers are surrounded by a uniform distribution of sources. In this case, the main contributions to the retrieved direct wave between the receivers come from sources in Fresnel zones around stationary points. The main application of direct-wave interferometry is the retrieval of seismic surface-wave responses from ambient noise and the subsequent tomographic determination of the surface-wave velocity distribution of the subsurface. Seismic interferometry is not restricted to retrieving direct waves between receivers. In a classic paper, Claerbout shows that the autocorrelation of the transmission response of a layered medium gives the plane-wave reflection response of that medium. This is essentially 1D reflect- ed-wave interferometry. Similarly, the crosscorrelation of the transmission responses, observed at two receivers, of an arbitrary inhomogeneous medium gives the 3D reflection response of that medium. One of the main applications of reflected-wave interferometry is retrieving the seismic reflection response from ambient noise and imaging of the reflectors in the subsurface. A common aspect of direct- and reflected-wave interferometry is that virtual sources are created at positions where there are only receivers without requiring knowledge of the subsurface medium parameters or of the positions of the actual sources.

INTRODUCTION

In this two-part tutorial, we give an overview of the basic principles and the underlying theory of seismic interferometry and discuss applications and new advances. The term seismic interferometry refers to the principle of generating new seismic responses of virtual sources by crosscorrelating seismic observations at different receiver locations. One can distinguish between controlled-source and passive interferometry. Controlled-source seismic interferometry, pioneered by Schuster (2001), Bakulin and Calvert (2004), and others, comprises a new processing methodology for seismic exploration data. Apart from crosscorrelation, controlled-source interferometry also involves summation of correlations over different source positions. Passive seismic interferometry, on the other hand, is a methodology for turning passive seismic measurements (ambient seismic noise or microearthquake responses) into deterministic seismic responses. Here, we further distinguish between retrieving surface-wave transmission responses (Campillo and Paul, 2003; Shapiro and Campillo, 2004; Sabra, Gerstoft, et al., 2005a) and exploration reflection responses (Claerbout, 1968; Scherbaum, 1987b; Draganov et al., 2007, 2009). In passive interferometry of ambient noise, no explicit summation of correlations over different source positions is required because the correlated responses are a superposition of simultaneously acting uncorrelated sources.

In all cases, the response that is retrieved by crosscorrelating two
receiver recordings (and summing over different sources) can be interpreted as the response that would be measured at one of the receivers as if there were a source at the other. Because such a point-source response is equal to a Green’s function convolved with a wavelet, seismic interferometry is also often called Green’s function retrieval. Both terms are used in this paper. The term interferometry is borrowed from radio astronomy, where it refers to crosscorrelation methods applied to radio signals from distant objects (Thompson et al., 2001). The name Green’s function honors George Green who, in a privately published essay, introduced the use of impulse responses in field representations (Green, 1828). Challis and Sheard (2003) give a brief history of Green’s life and theorem. Ramírez and Weglein (2009) review applications of Green’s theorem in seismic processing.

Early successful results of Green’s function retrieval from noise correlations were obtained in the field of ultrasonics (Weaver and Lobkis, 2001, 2002). The experiments were done with diffuse fields in a closed system. Here diffuse means that the amplitudes of the normal modes are uncorrelated but have equal expected energies. Hence, the crosscorrelation of the field at two receiver positions does not contain cross-terms of unequal normal modes. The sum of the remaining terms is proportional to the modal representation of the Green’s function of the closed system (Lobkis and Weaver, 2001). This means that the crosscorrelation of a diffuse field in a closed system converges to its impulse response. Later, it was recognized (e.g., Godin, 2007) that this theoretical explanation is akin to the fluctuation-dissipation theorem (Callen and Welton, 1951; Rytov, 1956; Rylov et al., 1989; Le Bellac et al., 2004).

The earth is a closed system; but at the scale of global seismology, the wavefield is far from diffuse. At the scale of exploration seismology, an ambient-noise field may have a diffuse character, but the encompassing system is not closed. Hence, for seismic interferometry, the normal-mode approach breaks down. Throughout this paper, we assume that the propagation velocity $c$ is constant and the medium is lossless. There are two receivers along the $x$-axis at $x_s$ and $x_h$. Figure 1b shows the response observed by the first receiver at $x_s$. We denote this response as $G(x_h, x_s, t)$, where $G$ stands for the Green’s function. Throughout this paper, we use the common convention that the first two arguments in $G(x_h, x_s, t)$ denote the receiver and source coordinates, respectively (here, $x_h$ and $x_s$), whereas the last argument denotes time $t$ or angular frequency $\omega$. In our example, this Green’s function consists of an impulse at $t = (x_h - x_s)/c$; therefore, $G(x_h, x_s, t) = \delta(t - (x_h - x_s)/c)$, where $\delta(t)$ is the Dirac delta function. Similarly, the response at $x_h$ is given by $G(x_h, x_s, t) = \delta(t - t_h)$, with $t_h = (x_h - x_s)/c$ (Figure 1c).

Seismic interferometry involves the crosscorrelation of responses at two receivers, in this case at $x_s$ and $x_h$. Looking at Figure 1a, it appears that the raypaths associated with $G(x_h, x_s, t)$ and $G(x_s, x_h, t)$ have the path from $x_h$ to $x_s$ in common. The traveltime along this common path cancels in the crosscorrelation process, leaving the crosscorrelation along the remaining path from $x_s$ to $x_h$, i.e., $t_h = t_s = (x_h - x_s)/c$. Hence, the crosscorrelation of the responses in Figure 1b and c is an impulse at $t_h = t_s$ (see Figure 1d). This impulse can be interpreted as the response of a source at $x_h$ observed by a receiver at $x_h$, i.e., the Green’s function $G(x_h, x_s, t)$. An interesting observation is that the propagation velocity $c$ and the position of the actual source $x_h$ need not be known. The traveltimes along the common path from $x_h$ to $x_s$ compensate each other, independent of the propagation velocity and the length of this path. Similarly, if the source impulse would occur at $t = t_h$ instead of $t = 0$, the impulses observed at $x_s$ and $x_h$ would be shifted by the same amount of time $t_h$, which would be canceled in the crosscorrelation. Thus, the absolute time $t_h$ at which the source emits its pulse need not be known.

Let us discuss this example a bit more precisely. We denote the crosscorrelation of the impulse responses at $x_h$ and $x_s$ as $G(x_h, x_s, t) = G(x_h, x_s, -t)$. The asterisk denotes temporal convolution, but the time reversal of the second Green’s function turns the convolution into a correlation, defined as $G(x_h, x_s, t) = G(x_h, x_s, -t) = \int G(x_s, x_s + t)G(x_s, x_h - t)dt'$. Substituting the delta functions into the right-hand side gives $\int \delta(t + t' - t_h)\delta(t' - t_s)dt' = \delta(t - (t_h - t_s))/c$. This is indeed the Green’s function $G(x_h, x_s, t)$, propagating from $x_s$ to $x_h$. Because we started this derivation with the crosscorrelation of the Green’s functions, we have obtained the following 1D Green’s function representation:

**DIRECT-WAVE INTERFEROMETRY**

**1D analysis of direct-wave interferometry**

We start our explanation of seismic interferometry by considering an illustrative 1D analysis of direct-wave interferometry. Figure 1a shows a plane wave, radiated by an impulsive unit source at $x = x_s$ and $t = 0$, propagating in the rightward direction along the $x$-axis. We assume that the propagation velocity $c$ is constant and the medium is lossless. There are two receivers along the $x$-axis at $x_s$ and $x_h$. Figure 1b shows the response observed by the first receiver at $x_s$. We denote this response as $G(x_h, x_s, t)$, where $G$ stands for the Green’s function. Throughout this paper, we use the common convention that the first two arguments in $G(x_h, x_s, t)$ denote the receiver and source coordinates, respectively (here, $x_h$ and $x_s$), whereas the last argument denotes time $t$ or angular frequency $\omega$. In our example, this Green’s function consists of an impulse at $t = (x_h - x_s)/c$; therefore, $G(x_h, x_s, t) = \delta(t - (x_h - x_s)/c)$, where $\delta(t)$ is the Dirac delta function. Similarly, the response at $x_h$ is given by $G(x_h, x_s, t) = \delta(t - t_h)$, with $t_h = (x_h - x_s)/c$ (Figure 1c).

Seismic interferometry involves the crosscorrelation of responses at two receivers, in this case at $x_h$ and $x_s$. Looking at Figure 1a, it appears that the raypaths associated with $G(x_h, x_s, t)$ and $G(x_s, x_h, t)$ have the path from $x_h$ to $x_s$ in common. The traveltime along this common path cancels in the crosscorrelation process, leaving the traveltime along the remaining path from $x_s$ to $x_h$, i.e., $t_h = t_s = (x_h - x_s)/c$. Hence, the crosscorrelation of the responses in Figure 1b and c is an impulse at $t_h = t_s$ (see Figure 1d). This impulse can be interpreted as the response of a source at $x_h$ observed by a receiver at $x_h$, i.e., the Green’s function $G(x_h, x_s, t)$. An interesting observation is that the propagation velocity $c$ and the position of the actual source $x_h$ need not be known. The traveltimes along the common path from $x_h$ to $x_s$ compensate each other, independent of the propagation velocity and the length of this path. Similarly, if the source impulse would occur at $t = t_h$ instead of $t = 0$, the impulses observed at $x_s$ and $x_h$ would be shifted by the same amount of time $t_h$, which would be canceled in the crosscorrelation. Thus, the absolute time $t_h$ at which the source emits its pulse need not be known.

Let us discuss this example a bit more precisely. We denote the crosscorrelation of the impulse responses at $x_s$ and $x_h$ as $G(x_h, x_s, t) = G(x_h, x_s, -t)$. The asterisk denotes temporal convolution, but the time reversal of the second Green’s function turns the convolution into a correlation, defined as $G(x_h, x_s, t) = G(x_h, x_s, -t) = \int G(x_s, x_h + t)G(x_s, x_h - t)dt'$. Substituting the delta functions into the right-hand side gives $\int \delta(t + t' - t_h)\delta(t' - t_s)dt' = \delta(t - (t_h - t_s))/c$. This is indeed the Green’s function $G(x_h, x_s, t)$, propagating from $x_s$ to $x_h$. Because we started this derivation with the crosscorrelation of the Green’s functions, we have obtained the following 1D Green’s function representation:
This representation formulates the principle that the crosscorrelation of observations at two receivers \((x_{A} \text{ and } x_{B})\) gives the response at one of those receivers \((x_{A})\) as if there were a source at the other receiver \((x_{B})\). It also shows why seismic interferometry is often called Green’s function retrieval.

Note that the source is not necessarily an impulse. If the source function is a wavelet instead of an impulse, the response observed at noise is 30 Hz; the figure shows only 4 s of a total of 160 s of noise.

In words: If the source function is a wavelet instead of an impulse, then the crosscorrelation of the responses at two receivers gives the Green’s function between these receivers, convolved with the autocorrelation of the source function.

This principle holds true for any source function, including noise. Figure 2a and b shows the responses at \(x_{A}\) and \(x_{B}\), respectively, of a bandlimited noise source \(N(t)\) at \(x_{B}\) (the central frequency of the noise is 30 Hz; the figure shows only 4 s of a total of 160 s of noise).

In this numerical example, the distance between the receivers is 1200 m and the propagation velocity is 2000 m/s; hence, the traveltime between these receivers is 0.6 s. As a consequence, the noise response at \(x_{A}\) in Figure 2b is 0.6 s delayed with respect to the response at \(x_{B}\) in Figure 2a (similar to the impulse in Figure 1c delayed with respect to the impulse in Figure 1b). Crosscorrelation of these noise responses gives, analogous to equation 2, the impulse response between \(x_{A}\) and \(x_{B}\), convolved with \(S_{A}(t)\), i.e., the autocorrelation of the noise \(N(t)\). The correlation is shown in Figure 2c, which indeed reveals a bandlimited impulse centered at \(t = 0.6\) s (the traveltime from \(x_{B}\) to \(x_{A}\)). Note that from registrations at two receivers of a noise field from an unknown source in a medium with unknown propagation velocity, we have obtained a bandlimited version of the Green’s function. By dividing the distance between the receivers (1200 m) by the traveltime estimated from the bandlimited Green’s function (0.6 s), we obtain an estimate of the propagation velocity between the receivers (2000 m/s). This illustrates that direct-wave interferometry can be used for tomographic inversion.

Until now, we considered a single plane wave propagating in the positive x-direction. In Figure 3a, we consider the same configuration as in Figure 1a, but now an impulsive unit source at \(x = x_{i}\) radiates a leftward-propagating plane wave. Figure 3b is the response at \(x_{A}\) given by \(G(x_{A},x_{B},t) = \delta(t - t'_{A})\), with \(t'_{A} = (x_{i} - x_{A})/c\). Similarly, the response at \(x_{B}\) is \(G(x_{B},x_{A},t) = \delta(t - t'_{B})\), with \(t'_{B} = (x_{i} - x_{B})/c\) (Figure 3c). The crosscorrelation of these responses gives \(\delta(t - (t'_{B} - t'_{A})) = \delta(t + (x_{B} - x_{A})/c)\), which is equal to the time-reversed Green’s function \(G(x_{B},x_{A},-t)\). So, for the configuration of Figure 3a, we obtain the following Green’s function representation:

\[
G(x_{B},x_{A},-t) = G(x_{B},x'_{B},t) \ast G(x'_{A},x_{S},-t). \tag{3}
\]

We can combine equations 1 and 3 as follows:

\[
G(x_{B},x_{A},t) + G(x_{B},x_{A},-t) = \sum_{i=1}^{2} G(x_{B},x_{A}^{(i)},t) \ast G(x_{A}^{(i)},x_{S},-t), \tag{4}
\]

where \(x_{A}^{(i)}\) or \(x_{B}^{(i)}\) for \(i = 1, 2\) stands for \(x_{A}\) or \(x_{B}\), respectively.

For the 1D situation, this combination may not seem very useful. We analyze it here, however, because this representation better resembles the 2D and 3D representations we encounter later. Note that because \(G(x_{B},x_{A},t)\) is the causal response of an impulse at \(t = 0\) (meaning it is nonzero only for \(t > 0\)), it does not overlap with \(G(x_{B},x_{A},-t)\) (which is nonzero only for \(t < 0\)). Hence, \(G(x_{B},x_{A},t)\) can be resolved from the left-hand side of equation 4 by extracting the causal part. If the source function is a wavelet \(s(t)\) with autocorrelation \(S_{A}(t)\), we obtain, analogous to equation 2,
Here, \( G(x_{B},x_{A},t) \) may have some overlap with \( G(x_{B},x_{A},-t) \) for small \( |t| \), depending on the length of the autocorrelation function \( S_{1}(t) \). Therefore, \( G(x_{B},x_{A},t) \) can be extracted from the left-hand side of equation 5, except for small distances \( |x_{B} - x_{A}| \).

The right-hand sides of equations 4 and 5 state that the crosscorrelation is applied to the responses of each source separately, after which the summation over the sources is carried out. For impulsive sources or transient wavelets \( s(t) \), these steps should not be interchanged. Let us see why. Suppose the sources at \( x_{A} \) and \( x_{B} \) act simultaneously, as illustrated in Figure 4a. Then the response at \( x_{A} \) would be given by \( u(x_{A},t) = \sum_{j=1}^{N} G(x_{A},x_{A}^{(j)},t) \ast s(t) \) and the response at \( x_{B} \) by \( u(x_{B},t) = \sum_{j=1}^{N} G(x_{B},x_{B}^{(j)},t) \ast s(t) \). These responses are shown in Figure 4b and c for an impulsive source \( s(t) = \delta(t) \). The crosscorrelation of these responses, shown in Figure 4d, contains two cross-terms at \( t_{B} - t_{A} \) and \( t_{B} - t_{A} \) that have no physical meaning. Hence, for impulsive or transient sources, the order of crosscorrelation and summation matters.

The situation is different for noise sources. Consider two simultaneously acting noise sources \( N_{1}(t) \) and \( N_{2}(t) \) at \( x_{A} \) and \( x_{B} \), respectively. The responses at \( x_{A} \) and \( x_{B} \) are given by \( u(x_{A},t) = \sum_{j=1}^{N} G(x_{A},x_{A}^{(j)},t) \ast N_{1}(t) \) and \( u(x_{B},t) = \sum_{j=1}^{N} G(x_{B},x_{B}^{(j)},t) \ast N_{2}(t) \), respectively (see Figure 5a and b). Because each of these responses is the superposition of a rightward- and a leftward-propagating wave, the response in Figure 5b is not a shifted version of that in Figure 5a (unlike the responses in Figure 2a and b). We assume that the noise sources are uncorrelated; thus, \( \langle N_{1}(t) \ast N_{2}(-t) \rangle = \delta_{0} S_{1}(t) \), where \( \delta_{0} \) is the Kronecker delta function and \( \langle \cdot \rangle \) denotes ensemble averaging. In practice, the ensemble averaging is replaced by integrating over sufficiently long time. In the numerical example the duration of the noise signals is again 160 s (only 4 s of noise is shown in Figure 5a and b). For the crosscorrelation of the responses at \( x_{A} \) and \( x_{B} \), we can now write

\[
\{G(x_{B},x_{A},t) + G(x_{B},x_{A},-t)\} \ast S_{1}(t)
= \sum_{i=1}^{2} u(x_{B},x_{B}^{(i)},t) \ast u(x_{A},x_{A}^{(i)},-t).
\] (5)

Combining equation 6 with equation 4, we finally obtain

\[
\{G(x_{B},x_{A},t) + G(x_{B},x_{A},-t)\} \ast S_{N}(t) = \langle u(x_{B},t) \ast u(x_{A},-t) \rangle.
\] (7)

Expression 7 shows that the crosscorrelation of two observed fields at \( x_{A} \) and \( x_{B} \), each of which is the superposition of rightward- and leftward-propagating noise fields, gives the Green’s function between \( x_{A} \) and \( x_{B} \) plus its time-reversed version, convolved with the autocorrelation of the noise (see Figure 5c). The cross-terms, unlike Figure 4d, do not contribute because the noise sources \( N_{1}(t) \) and \( N_{2}(t) \) are uncorrelated.

Miyazawa et al. (2008) apply equation 7 with \( x_{A} \) and \( x_{B} \) at different depths along a borehole in the presence of industrial noise at Cold Lake, Alberta, Canada. By choosing for \( u \) different components of multicomponent sensors in the borehole, they retrieve separate Green’s functions for P- and S-waves, the latter with different polarizations. From the arrival times in the Green’s functions, they derive the different propagation velocities and accurately quantify shearwave splitting.

Despite the relative simplicity of our 1D analysis of direct-wave interferometry, we can make several observations about seismic interferometry that also hold true for more general situations. First, we can distinguish between interferometry for impulsive or transient
sources on the one hand (equations 4 and 5) and interferometry for noise sources on the other hand (equation 7). In the case of impulsive or transient sources, the responses of each source must be crosscorrelated separately, after which a summation over the sources takes place. In the case of uncorrelated noise sources, a single crosscorrelation suffices.

Second, it appears that an isotropic illumination of the receivers is required to obtain a time-symmetric response between the receivers (of which the causal part is the actual response). In one dimension, isotropic illumination means equal illumination by rightward- and leftward-propagating waves. In two and three dimensions, it means equal illumination from all directions (discussed in the next section).

Finally, instead of the time-symmetric response \( G(x_p, x_s, t) + G(x_p, x_s, -t) \), in the literature we often encounter an antisymmetric response \( G(x_p, x_s, t) - G(x_p, x_s, -t) \). This is merely a result of differently defined Green’s functions. Note that a simple time differentiation of the Green’s functions would turn the symmetric response into an antisymmetric one, and vice versa (see Wapenaar and Fokkema [2006] for a more detailed discussion on this aspect).

2D and 3D analysis of direct-wave interferometry

We extend our discussion of direct-wave interferometry to configurations with more dimensions. In the following discussion, we mainly use heuristic arguments, illustrated with a numerical example. For a more precise derivation based on stationary-phase analysis, we refer to Snieder (2004).

Consider the 2D configuration shown in Figure 6a. The horizontal dashed line corresponds to the 1D configuration of Figure 1a, with two receivers at \( x_A \) and \( x_B \), 1200 m apart (\( x \) denotes a Cartesian coordinate vector). The propagation velocity \( c \) is 2000 m/s, and the medium is again assumed to be lossless. Instead of plane-wave sources, we have many point sources denoted by the small black dots, distributed over a “pineapple slice,” emitting transient signals with a central frequency of 30 Hz. In polar coordinates, the positions of the sources are denoted by \((r_s, \phi_s)\). The angle \( \phi_s \) is equidistantly sampled \((\Delta \phi_s = 0.25^\circ)\), whereas the distance \( r_s \) to the center of the slice is chosen randomly between 2000 and 3000 m. The responses at the two receivers at \( x_A \) and \( x_B \) are shown in Figure 6b and c, respectively, as a function of the (polar) source coordinate \( \phi_s \) (for display purposes, only every sixteenth trace is shown). These responses are crosscorrelated (for each source separately), and the crosscorrelations are shown in Figure 6d, again as a function of \( \phi_s \). Such a gather is often called a correlation gather. Note that the traveltimes in this correlation gather vary smoothly with \( \phi_s \), despite the randomness of the traveltimes in Figure 6b and c. This is because in the crosscorrelation process only the time difference along the paths to \( x_A \) and \( x_B \) matters.

The source in Figure 6a with \( \phi_s = 0^\circ \) plays the same role as the plane-wave source at \( x_A \), in Figure 1a. For this source, the crosscorrelation gives a signal at \( |x_B - x_A|/c = 0.6 \) s, seen in the trace at \( \phi_s = 0^\circ \) in Figure 6d. Similarly, the source at \( \phi_s = 180^\circ \) plays the same role as the plane-wave source at \( x_B \) in Figure 3a and leads to the trace at \( \phi_s = 180^\circ \) in Figure 6d with a signal at \(-0.6 \) s. Analogous to equation 5, we sum the crosscorrelations of all sources, i.e., we sum...
all traces in Figure 6d, which leads to the time-symmetric response in Figure 6e, with two events at 0.6 and −0.6 s. These two events are again interpreted as the response of a source at $x_8$, observed at $x_8$, plus its time-reversed version, i.e., $\{G(x_8,x_i,t) + G(x_8,x_i,-t)\} * S_0(t)$, where $S_0(t)$ is the autocorrelation of the source waveform. Because the sources have a finite frequency content, not only do the sources exactly at $\theta_0 = 0^\circ$ and $\theta_0 = 180^\circ$ contribute to these events but also the sources in Fresnel zones around these angles. These Fresnel zones are denoted by the thick dashed lines in Figure 6a and d. In Figure 6d, the centers of these Fresnel zones are the stationary points of the traveltime curve of the crosscorrelations. Note that the events in all traces outside the Fresnel zones in Figure 6d interfere destructively and give no coherent contribution in Figure 6e. The noise between the two events in Figure 6e results because the traveltime curve in Figure 6d is not 100% smooth, caused by the randomness of the source positions in Figure 6a.

The response in Figure 6e is obtained by summing crosscorrelations of independent transient sources. Using the arguments in the previous section, we can replace the transient sources with simultaneously acting noise sources. The cross-terms disappear when the noise sources are uncorrelated; hence, a single crosscorrelation of independent transient sources. Using the arguments in the sense that energy propagates equally in all directions, but where the scattered waves excited by a single source are equipartitioned, in the fundamental mode is considered, surface waves can be seen as an approximate solution of a 2D wave equation with a frequency-dependent propagation velocity. So by considering the 2D configuration of Figure 6a as a plan view, the analysis above holds for ambient seismic noise. The Green’s function of the fundamental mode of the direct surface wave can thus be extracted by crosscorrelating ambient-noise recordings at two seismometers. When many seismometers are available, this procedure can be repeated for any combination of two seismometers. In other words, each seismometer can be turned into a virtual source, the response of which is observed by all other seismometers.

Figure 7, reproduced with permission from Lin et al. (2009), shows a beautiful example of the Rayleigh-wave response of a virtual source southeast of Lake Tahoe, California, U.S.A. The white triangles represent more than 400 seismometers (USArray stations). Ocean-generated ambient seismic noise (Longuet-Higgins, 1950; Webb, 1998; Stehly et al., 2006) was recorded between October 2004 and November 2007. Because this noise is coming from the ocean, it is far from isotropic. This means the crosscorrelation of the noise between any two stations does not yield time-symmetric results such as those in Figure 6. However, as long as one of the Fresnel zones is sufficiently covered with sources, it is possible to retrieve either $G(x_8,x_i,t) * S_0(t)$ or $G(x_8,x_i,-t) * S_0(t)$ (note that the location and shape of the Fresnel zone is different for each combination of stations). The snapshots shown in Figure 7a and b were obtained by crosscorrelating the noise recorded at the station denoted by the star with noise recorded at all other stations. The amplitudes exhibit azimuthal variation due to the anisotropic illumination. Responses such as this are used for tomographic inversion of the Rayleigh-wave velocity of the crust and for measuring azimuthal anisotropy in the crust.
Bensen et al. (2007) show that it is possible to retrieve the Rayleigh-wave velocity as a function of frequency. Brenguier et al. (2007) combine these approaches to 3D tomographic inversion. From noise measurements at the Piton de la Fournaise volcano, they have retrieved the Rayleigh-wave group velocity distribution as a function of frequency and used this to derive a 3D S-wave velocity model of the interior of the volcano. In the past couple of years, the applications of direct surface-wave interferometry have expanded spectacularly. Without any claim of completeness, we mention Larose et al. (2005), Gerstoff et al. (2006), Kang and Shin (2006), Larose et al. (2006), Yao et al. (2006), Bensen et al. (2008), Gouédard et al. (2008a, 2008b), Liang and Langston (2008), Lin et al. (2008), Ma et al. (2008), Yao et al. (2008), Li et al. (2009), and Piccozzi et al. (2009). The success of these applications is explained by the fact that surface waves are by far the strongest events in ambient seismic noise. In the next section, we show that the retrieval of reflected waves from ambient seismic noise is an order more difficult.

Direct surface-wave interferometry has an interesting link with early work by Aki (1957, 1965) and Toksöz (1964) on the spatial autocorrelation (SPAC) method. The SPAC method uses a circular array of seismometers plus a seismometer at the center of the circle. For a distribution of uncorrelated fundamental-mode Rayleigh waves propagating as plane waves in all directions, the spatial autocorrelation function obtained from the circular array reveals the local surface-wave velocity as a function of frequency and, subsequently, the local depth-dependent velocity profile. An important difference with the interferometry approach is that the distances between the receivers in the SPAC method are usually smaller than half a wavelength (Henstridge, 1979), making it a local method; whereas in direct-wave interferometry, the distances are assumed much larger than the wavelength because otherwise the stationary-phase arguments would not hold. More recent discussions on the SPAC method are given by Okada (2003, 2006) and Asten (2006). An interesting discussion on the relation between the SPAC method and seismic interferometry is given by Yokoi and Margaryan (2008).

REFLECTED-WAVE INTERFEROMETRY

1D analysis of reflected-wave interferometry

The figure on the cover of Schuster’s book on seismic interferometry (Schuster, 2009), reproduced in Figure 8, explains the basic principle of reflected-wave interferometry very well. Figure 8a shows a source in the subsurface that radiates a transient wave to the earth’s surface, where it is received by a geophone. The trace contains the delayed source wavelet. Figure 8b shows how the wave is reflected downward by the surface, reflected upward again by a scatterer in the subsurface, and received by a second geophone at the earth’s surface. The trace contains the wavelet, which is further delayed due to the propagation along the additional path from receiver 1 via the scatterer to receiver 2. The propagation paths in Figure 8a and b have the path from the subsurface source to the first receiver in common. By crosscorrelating the two traces (Schuster denotes this by ⊗), the propagation along this common path is eliminated, leaving the path from receiver 1 via the scatterer to receiver 2 (Figure 8c). Hence, the result can be interpreted as a reflection experiment with a source at the position of the first geophone, of which the reflection response is received by the second geophone.

Let us see how this method deals with multiple reflections. To this end, we consider a configuration consisting of a homogeneous lossless layer, sandwiched between a free surface and a homogeneous lossless half-space (Figure 9a). An impulsive unit source in the lower half-space emits a vertically upward-propagating plane wave that reaches the surface after a time $t_0$. Because it was transmitted by a single interface on its way to the surface, the first arrival is given by $\tau \delta(t-t_0)$, where $\tau$ is the transmission coefficient of the interface (we use lowercase symbols for local transmission and reflection coefficients). This arrival is represented by the impulse at $t = t_0$ in Figure 9b. The wave is reflected downward by the free surface (reflection coefficient $-1$) and subsequently reflected upward by the interface (reflection coefficient $r$). Therefore, the next arrival reaching the surface is $-r \tau \delta(t-t_0-\Delta t)$, with $\Delta t = 2\Delta z/c$, where $\Delta z$ is the thickness of the first layer and $c$ its propagation velocity. Figure 9b shows the total upgoing wavefield reaching the free surface — denoted as $T(t)$, where $T$ stands for the global transmission response. It consists of an infinite series of impulses with regular intervals $\Delta t$ (starting at $t_0$) and amplitudes $a_0 = \tau$, $a_1 = -r\tau$, $a_2 = r^2\tau$, $a_3 = -r^3\tau$, etc.

Seismic interferometry for a vertically propagating plane wave reduces to evaluating the autocorrelation of the global transmission response, i.e., $T(t) * T(-t)$. We obtain the simplest result if we consider so-called power-flux normalized up- and downgoing waves (Frasier, 1970; Kennett et al., 1978; Ursin, 1983; Chapman, 1994). This means we define the local transmission coefficient $\tau$ as the square root of the product of the transmission coefficients for acoustic pressure and particle velocity. Hence, for an upgoing wave, $\tau = \sqrt{(1-r)(1+r)} = \sqrt{1-r^2}$ (which is also the transmission coefficient for a downgoing wave). The autocorrelation for zero time lag is

$$a_0^2 + a_1^2 + a_2^2 + \cdots + \delta(t) = \tau^2(1 + r^2 + r^4 + r^6 + \cdots) \delta(t) = \tau^2(1 - r^2)^{-1} \delta(t) = \delta(t).$$

This is represented by the impulse at $t = 0$ in Figure 9c. The autocorrelation for time lag $\Delta t$ is

$$(a_1 a_0 + a_2 a_1 + a_3 a_2 + \cdots) \delta(t-\Delta t) = -r \tau^2(1 + r^2 + r^4 + \cdots) \delta(t-\Delta t) = -r \delta(t-\Delta t),$$

which is represented by the impulse at $\Delta t$ in Figure 9c. For time lags 2$\Delta t$, 3$\Delta t$, etc., we obtain $r^2 \delta(t-2\Delta t)$, $-r^3 \delta(t-3\Delta t)$, etc. Apart from an overall minus sign, these impulses together (except the one at $t = 0$) represent the global reflection response $R(t)$ of a downgoing wave.
ing plane wave, illuminating the medium from the free surface. Consequently, the causal part of the autocorrelation is equal to $-R(t)$. Similarly, the acausal part is $-R(-t)$. Taking everything together, we have $T(t) \ast T(-t) = \delta(t) - R(t) - R(-t)$, or

$$R(t) + R(-t) = \delta(t) - T(t) \ast T(-t).$$  

(8)

Expression 8 shows that the global reflection response can be obtained from the autocorrelation of the global transmission response. This concept can be understood intuitively if one bears in mind that the reflection response, including all its multiples, is implicitly present in the coda of the transmission response (see Figure 9b). Note the analogy of equation 8 with the expression for direct-wave interferometry (equation 4). In both cases, the left-hand side is a superposition of a causal response and its time-reversed version. The main difference is that the right-hand side of equation 4 is a superposition of crosscorrelations of rightward- and leftward-propagating waves, which was necessary to get the time-symmetric response, whereas the right-hand side of equation 8 is a single autocorrelation.

The free surface in Figure 9a acts as a mirror, which removes the reflection response, including all its multiples, from the global transmission response. Consequently, the causal part of the autocorrelation is equal to

$$\hat{f}(\omega) = \int_{-\infty}^{\infty} f(t) \exp(-j\omega t) dt,$$

(9)

where $\omega$ is the angular frequency and $j$ the imaginary unit. The net power flux just below the free surface is given by

$$\hat{D} \hat{D}^* - \hat{U} \hat{U}^* = (1 - \hat{R})(1 - \hat{R}^*) - \hat{R} \hat{R}^* = 1 - \hat{R} - \hat{R}^*,$$

(10)

where the superscript asterisk denotes complex conjugation. The net power flux is independent of depth, so the right-hand side of equation 10 is equal to the net power flux in the lower half-space $\hat{T} \hat{T}^*$. Thus, $1 - \hat{R} - \hat{R}^* = \hat{T} \hat{T}^*$, or

$$\hat{R} + \hat{R}^* = 1 - \hat{T} \hat{T}^*.$$  

(11)

Complex conjugation in the frequency domain corresponds to time reversal in the time domain, so the inverse Fourier transform of this equation again gives equation 8, which has now been proven to hold for arbitrarily layered media.

The central assumption in this derivation is the conservation of acoustic power, which of course only holds in lossless media. We assumed in our discussions of direct-wave interferometry that the medium was lossless; but in the present derivation, the essence of this

---

**Figure 9.** From transmission to reflection response (1D). (a) Simple layered medium with an upgoing plane wave radiated by a source in the lower half-space. (b) The transmission response $T(t)$ observed at the free surface. (c) The autocorrelation $T(t) \ast T(-t)$. The causal part is, apart from a minus sign, the reflection response $R(t)$. (d) Configuration used to derive the same relation for an arbitrarily layered medium.
assumption has become manifest. Most approaches to seismic interferometry rely on the assumption that the medium is lossless. In Part 2 of this tutorial, we also encounter approaches that account for losses or that use the essence of this assumption to estimate loss parameters.

We should note here that equation 8 for arbitrarily layered media was derived more than 40 years ago by Jon Claerbout at Stanford University (Claerbout, 1968). His expression looks slightly different because he did not use flux normalization. For his derivation, he used a recursive method introduced by Thomson (1950), Haskell (1953), and others. Later, he proposed the shorter derivation using energy conservation (Claerbout, 2000). Fraasier (1970) generalizes Claerbout’s result for obliquely propagating plane P- and SV-waves in a horizontally layered elastic medium.

Analogous to equations 5 and 7, equation 8 can be modified for transient or noise signals. For example, let $\mu(t) = T(t) + N(t)$ be the upgoing wavefield at the surface, with $N(t)$ representing the noise signal emitted by the source in the lower half-space. Then we obtain from equation 8

$$\{R(t) + R(-t)\} \cdot S_\mu(t) = S_\mu(t) - \langle \mu(t) \cdot \mu(-t) \rangle,$$

where $S_\mu(t)$ is the autocorrelation of the noise. Equation 12 shows that the autocorrelation of passive noise measurements gives the reflection response of a transient source at the surface. Quite remarkable indeed! Again, the position of the actual source does not need to be known, but it should lie below the lowest interface. In the next section, we show that the latter assumption can be relaxed in 2D and 3D configurations.

### 2D and 3D analysis of reflected-wave interferometry

Claerbout conjectured for the 2D and 3D situation that “by crosscorrelating noise traces recorded at two locations on the surface, we can construct the wavefield that would be recorded at one of the locations if there was a source at the other” (citation is from Rickett and Claerbout [1999], but the conjecture is also mentioned by Cole [1995]). This statement could be applied literally to direct-wave interferometry, as discussed in a previous section, but Claerbout’s conjecture concerns reflected-wave interferometry. Of course, this terminology was not used by these authors, and the links between direct-wave and reflected-wave interferometry were discovered several years later. Duvall et al. (1993) and Rickett and Claerbout (1999) applied crosscorrelations to noise observations at the surface of the sun and were able to retrieve helioseismological shot records.

Claerbout’s 1D relation (equation 8) and his conjecture for the 3D situation inspired Jerry Schuster at the University of Utah. During a sabbatical in 2000 at Stanford University, Schuster analyzed the conjecture by the method of stationary phase. Let us briefly review his line of thought (Schuster, 2001; Schuster et al., 2004; Schuster and Zhou, 2006). First, consider again the configuration shown in Figure 8. It was implicitly assumed that the first geophone is located precisely at the specular reflection point of the drawn ray in Figure 8b. As a consequence, the ray in Figure 8a coincides with the first branch of the ray in Figure 8b; so in a 1D crosscorrelation process, the travelt ime along this ray cancels, which leaves the travelt ime of the reflection response. In practice, the source position and hence the position of the specular reflection point are unknown. However, when there are multiple (unknown) sources in the subsurface, it is again possible to extract the reflection response.

To see this, consider the situation depicted in Figure 10a, in which there are multiple sources buried in the subsurface. The ray that leaves the source at $x_{1,s} = -300$ m reflects at $x_4$ (the position of the first geophone) on its way to the scatterer at $x_6$ and the second geophone at $x_8$; this is the specular ray. The rays leaving the other sources have their specular reflection points left and right from $x_4$ (the solid rays in Figure 10a). The direct arrivals at $x_4$ follow the dashed paths and do not coincide with the solid rays, except for the source at $x_{1,s} = -300$ m. For each of the sources, we crosscorrelate the direct arrival at $x_4$ with the scattered wave recorded at $x_8$. This gives the correlation gather shown in Figure 10, in which the horizontal axis denotes the source coordinate $x_{1,s}$. The trace at $x_{1,s} = -300$ m shows an impulse (indicated by the vertical arrow) at $t_{AB}$, which is the travelt ime from $x_4$ via the scatterer to $x_8$. The impulses in the surrounding traces arrive before $t_{AB}$.

If we sum the traces for all $x_{1,s}$, the main contribution comes from an area (the Fresnel zone, indicated by the dashed lines) around the point $x_{1,s} = -300$ m where the travelt ime curve is stationary (indicated by the vertical arrow), the other contributions cancel. Hence, the sum of the correlations (Figure 10c) contains an impulse at $t_{AB}$ and can be interpreted as the reflection response that would be mea-

---

**Figure 10.** Basic principle of reflected-wave interferometry revisited. (a) Configuration with multiple sources in the subsurface. Only the ray emitted by the source at $x_{1,s} = -300$ m has its specular reflection point at one of the geophone positions. (b) Correlation response of the rays at $x_4$ and $x_8$ as a function of the source coordinate $x_{1,s}$. The travelt ime curve connecting these events is stationary at $x_{1,s} = -300$ m. The thick dashed lines indicate the Fresnel zone. (c) The sum of the correlations in (b). This is interpreted as the reflection response of a source at $x_4$ observed by a receiver at $x_8$. 

---
sured at $x_2$ if there were a source at $x_1$. In other words, the source has been repositioned from its unknown position at depth to a known position $x_1$ at the surface. Note that this procedure works for any $x_1$ and $x_2$ as long as the array of sources contains a source that emits a specular ray via $x_1$ and the scatterer to $x_2$. In Appendix A, we give a simple proof that the stationary point of the traveltime curve in a correlation gather corresponds to the source from which the rays to $x_1$ and $x_2$ leave in the same direction.

This example shows that it is possible to reposition (or redatum) sources without knowing the velocity model and the position of the original sources. In exploration geophysics, redatuming is known as a process that brings sources and/or receivers from the acquisition level to another depth level, using extrapolation operators based on a macro velocity model (Berryhill, 1979, 1984). In seismic interferometry, as illustrated in Figure 10, the extrapolation operator comes directly from the data (in this example, the observed direct wave at $x_1$).

In the years following his sabbatical, Schuster showed that the interferometric redatuming concept, indicated in Figure 10, can be applied to a wide range of configurations (mostly for controlled-source data). His work inspired many other researchers to develop interferometric methods for exploration geophysics. For example, VSP data can be transformed into crosswell data (Minato et al., 2007) or into single-well reflection profiles to improve salt-flank delineation and imaging (Willis et al., 2006; Xiao et al., 2006; Hornby and Yu, 2007; Lu et al., 2008). Interferometry can be used to turn multiples in VSP data into primaries and in this way enlarge the illuminated area (Yu and Schuster, 2006; He et al., 2007; Jiang et al., 2007). Surface multiples can be turned into primaries at the position of missing traces (Wang et al., 2009). Crosscorrelation of refracted waves gives virtual refractions that can be used for improved estimation of the subsurface parameters (Dong et al., 2006b; Mikesell et al., 2009). Surface waves can be predicted by interferometry and subsequently subtracted from exploration seismic data (Curtis et al., 2006; Dong et al., 2006a; Halliday et al., 2007, 2010; Xue et al., 2009). In his recent book, Schuster (2009) systematically discusses all possible interferometric transformations between surface data, VSP data, single-well profiles, and crosswell data. Figure 11 shows some examples. Another approach to interferometric redatuming of controlled-source data, known as the virtual-source method (Bakulin and Calvert, 2004, 2006), is discussed in Part 2 of this paper.

The example discussed in Figure 10 deals with primary reflections and therefore confirms Claerbout’s conjecture only partly. The 1D analysis in the previous section showed that not only primary reflections but also all multiples are recovered from the autocorrelation of the transmission response. Claerbout’s conjecture for the 3D situation can be proven along similar lines. Instead of using the principle of power conservation, a so-called power reciprocity theorem is used as the starting point. In general, an acoustic reciprocity theorem formulates a relation between two acoustic states (de Hoop,
Consider the configuration in Figure 12a. An arbitrary inhomogeneous lossless medium is sandwiched between a free surface and a homogeneous lower half-space. Impulsive sources are distributed along a horizontal plane in this lower half-space. For this configuration, we derive (Wapenaar et al., 2002, 2004)

\[ R(x_B, x_A, t) + R(x_B, x_A, -t) \]

\[ = \delta(x_{H,B} - x_{H,A}) \delta(t) - \sum_s T(x_{B, s}, x_A, t) + T(x_A, x_{B, s}, t). \]

(13)

Here, \( x_{H,A} \) and \( x_{H,B} \) denote the horizontal components of \( x_A \) and \( x_B \), respectively; \( T(x_{A, s}, x_{B, s}, t) \) is the upcoming transmission response of an impulsive point source at \( x_{B, s} \) in the subsurface, observed at \( x_{A, s} \) at the free surface. Its coda includes all surface-related and internal multiple reflections (only a few rays are shown in Figure 12a). The right-hand side of equation 13 involves a crosscorrelation of transmission responses at \( x_A \) and \( x_B \) for each source \( x_{B, s} \), followed by a summation over all source positions. The time-symmetric response on the left-hand side is the reflection response that would be recorded at \( x_B \) if there were a source at \( x_A \), plus its time-reversed version. The main approximation is the negligence of evanescent waves. Apart from that, the retrieved reflection response \( R(x_B, x_A, t) \) contains all primary, surface-related, and internal multiple reflections. They are unraveled by equation 13 from the coda of the transmission responses.

When the impulsive sources are replaced by uncorrelated noise sources, then the responses at \( x_A \) and \( x_B \) are given by \( u(x_A, t) = \sum_s T(x_{A, s}, x_{B, s}, t) + N_s(t) \) and \( u(x_B, t) = \sum_s T(x_{B, s}, x_{A, s}, t) + N_s(t) \) (see Figure 12b), where each dashed ray represents a complete transmission response). Using a derivation similar to the one that transforms equation 4 into equation 7, we obtain from equation 13

\[ \{R(x_B, x_A, t) + R(x_B, x_A, -t)\} S(t) \]

\[ = \delta(x_{H,B} - x_{H,A}) S(t) - \langle u(x_B, t) + u(x_A, t) \rangle, \]

(14)

where \( S(t) \) is the autocorrelation of the noise.

Equation 14 shows that the direct crosscorrelation of passive noise measurements gives the reflection response of a transient source at the free surface. Although equations 13 and 14 are derived for a situation in which the sources at \( x_{B, s} \) lie at the same depth (Figure 12a), these equations remain approximately valid when the depths are randomly distributed (as in Figure 12b) because in the crosscorrelation process, only the time difference matters (we used a similar reasoning for direct-wave interferometry to explain why the traveltime curves in Figure 6d remain smooth). Moreover, despite the initial assumption that the medium is homogenous below the sources, Draganov et al. (2004) show with numerical examples that the randomness of the source depths helps to suppress nonphysical ghosts related to reflectors below the sources, whereas the physical response of these deeper reflectors shows up correctly in \( R(x_B, x_A, t) \). This has also been explained with theoretical arguments (Wapenaar and Fokkema, 2006).

Equations 13 and 14 are used by various authors to turn ambient seismic noise into virtual exploration seismic reflection data (Draganov et al., 2006, 2007, 2009; Hohl and Mateeva, 2006; Torri et al., 2007). Interestingly, the teleseismic community has recognized independently that the coda of transmission responses from distant sources contains reflection information which can be used to image the earth’s crust (Bostock et al., 2001; Rondenay et al., 2001; Shragge et al., 2001, 2006; Mercier et al., 2006). The link between teleseismic coda imaging and seismic interferometry is exploited by Kumar and Bostock (2006), Nowack et al. (2006), Chaput and Bostock (2007), and Tonegawa et al. (2009).

We conclude this section with an example of retrieving virtual exploration seismic reflection data from ambient noise, recorded by Shell in a desert area near Ajdabiya, Libya. Figure 13a shows 10 s of noise, arbitrarily selected from 11 hours of noise, recorded along a 20-km line. Each receiver channel represents a group of 48 vertical-component geophones, designed to suppress surface waves. Nevertheless, the main events in Figure 13a are parts of the surface waves that fell outside the suppression band of the geophone groups; these surface waves were caused by traffic on a road intersecting the line at \( x_1 = 14 \) km. Band-pass and frequency-wavenumber \( (f-k) \) filtering were used to suppress the surface waves further (Figure 13b).

![Figure 12](http://segdl.org/)
We use equation 14 to retrieve the reflection response. Strictly speaking, equation 14 requires decomposition of the filtered geophone data of Figure 13b into the upgoing transmission response. In the acoustic approximation, decomposition mainly involves the application of an angle-dependent amplitude filter. Because it is very difficult to obtain true amplitude responses from ambient noise anyway, the decomposition step is skipped. Using equation 14, with $x_1$ fixed ($x_{1,A} = 1$ km) and $x_0$ chosen variable ($x_{1,B} = 0, \ldots, 4$ km), we retrieve a seismic shot record $R(x_0, x_1, t)$ from the noise, of which the first 2.5 s are shown in Figure 14a. The red star at $x_{1,B} = x_{1,A} = 1$ km denotes the position of the virtual source. An active seismic reflection experiment, carried out with the source at the same position, is shown in Figure 14b. Particularly in the red areas, the reflections retrieved from the ambient noise (Figure 14a) correspond quite well with those in the active shot gather (Figure 14b). For more details about this experiment as well as a pseudo-3D reflection image obtained from the ambient noise, see Draganov et al. (2009).

**CONCLUSIONS**

We have discussed the basic principles of seismic interferometry in a heuristic way. We have shown that, whether we consider controlled-source or passive interferometry, virtual sources are created at positions where there are only receivers. Of course, no new information is generated by interferometry, but information hidden in noise or in a complex scattering coda is reorganized into easily interpretable responses that can be further processed by standard tomographic inversion or reflection-imaging methodologies. The main strength is that this information unraveling requires no knowledge of the subsurface medium parameters nor of the positions or timing of the actual sources. Moreover, the processing consists of simple crosscorrelations and is almost entirely data driven.

In Part 2, we discuss the relation between interferometry and time-reversed acoustics, review a mathematically sound derivation, and indicate recent and new advances.

**ACKNOWLEDGMENTS**

This work is supported by the Netherlands Research Centre for Integrated Earth Science (ISES), the Dutch Technology Foundation (STW) (grant VENI.08.115), and by the U. S. National Science Foundation (NSF) (grant EAS-0609595). We thank associate editor Sven Treitel and reviewers Jerry Schuster, Kasper van Wijk, and Mark Willis for their valuable comments and suggestions, which improved this paper. We are grateful to Jerry Schuster, Fan-Chi Lin, Mike Ritzwoller, and Wiley-Blackwell (publisher of Geophysical Journal International) for Figures 11 and 7. Last but not least, we thank the Libyan National Oil Company for permission to publish the Ajdabaya data results and Shell in Libya for collecting and making available the passive data.

**APPENDIX A**

**STATIONARY-PHASE ANALYSIS**

We give a simple proof that the stationary point of the traveltime curve in a correlation gather corresponds to the source from which the rays to the receivers at $x_A$ and $x_B$ leave in the same direction. Consider two rays $A$ and $B$ that propagate from an arbitrary source point to the two receivers (Figure A-1). This propagation may be direct, or it may involve bounces off reflectors or scatterers; the fate of these rays is irrelevant for the argument presented here. The sources involved in interferometry are located on the surface, indicated by the dashed line in Figure A-1. This surface, which need not be planar, is in three dimensions parameterized by two orthogonal coordinates $q_1$ and $q_2$. We first keep $q_2$ fixed and consider only variations in $q_1$.

The traveltime from a given source to the receiver at $x_A$ is denoted by $t_A$, and the traveltime from that source to the receiver at $x_B$ is denoted by $t_B$. These traveltimes are, in general, functions of the source position $q_1$. In seismic interferometry, the traveltimes of the sources
Figure A-1. Two rays, A and B, that propagate from a common point on the surface with sources (dashed line) and their take-off angles at this source surface.

that are crosscorrelated are subtracted. This means that the traveltime $t_{\text{cor}}$ of the crosscorrelation for a given source position is

$$t_{\text{cor}}(q_1) = t_B(q_1) - t_A(q_1). \tag{A-1}$$

The condition that the traveltime is stationary means that

$$\frac{\partial t_{\text{cor}}(q_1)}{\partial q_1} = \frac{\partial t_B(q_1)}{\partial q_1} - \frac{\partial t_A(q_1)}{\partial q_1} = 0. \tag{A-2}$$

A standard derivation (Aki and Richards, 1980) relates the slowness along the surface to the take-off angle

$$\frac{\partial q_1}{\partial q_1} = \sin i_A \quad \frac{c}{\partial q_1}, \tag{A-3}$$

with $c$ the propagation velocity. A similar expression holds for $t_B$. Inserting this in equation A-2 implies that, at the stationary point,

$$i_A = i_B, \tag{A-4}$$

which means the rays take off in the same direction.

This reasoning is applicable to variations in the source coordinate $q_1$. The same reasoning applies to variations with the orthogonal source coordinate $q_2$. The rays take off in the same direction as measured in two orthogonal planes; hence, the rays have the same direction in three dimensions. Therefore, the rays radiating from the stationary source position are parallel.
