Abstract. Ground-based Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) measurements of nitrous acid (HONO) and its precursor NO$_2$ (nitrogen dioxide) as well as aerosols have been performed daily in Beijing city centre (39.98$^\circ$N, 116.38$^\circ$E) from July 2008 to April 2009 and at the suburban site of Xianghe (39.75$^\circ$N, 116.96$^\circ$E) located ∼60 km east of Beijing from March 2010 to December 2012. This extensive dataset allowed for the first time the investigation of the seasonal cycle of HONO as well as its diurnal variation in and in the vicinity of a megacity. Our study was focused on the HONO and NO$_2$ near-surface concentrations (0–200 m layer) and total vertical column densities (VCDs) and also aerosol optical depths (AODs) and extinction coefficients retrieved by applying the Optimal Estimation Method to the MAX-DOAS observations. Monthly averaged HONO near-surface concentrations at local noon display a strong seasonal cycle with a maximum in late fall/winter (∼0.8 and 0.7 ppb at Beijing and Xianghe, respectively) and a minimum in summer (∼0.1 ppb at Beijing and 0.03 ppb at Xianghe). The seasonal cycles of HONO and NO$_2$ appear to be highly correlated, with correlation coefficients in the 0.7–0.9 and 0.5–0.8 ranges at Beijing and Xianghe, respectively. The stronger correlation of HONO with NO$_2$ and also with aerosols observed in Beijing suggests possibly larger role of NO$_2$ conversion into HONO in the Beijing city center than at Xianghe. The observed diurnal cycle of HONO near-surface concentration shows a maximum in the early morning (about 1 ppb at both sites) likely resulting from night-time accumulation, followed by a decrease to values of about 0.1–0.4 ppb around local noon. The HONO/NO$_2$ ratio shows a similar pattern with a maximum in the early morning (values up to 0.08) and a decrease to ∼0.01–0.02 around local noon. The seasonal and diurnal cycles of the HONO near-surface concentration are found to be similar in shape and in relative amplitude to the corresponding cycles of the HONO total VCD and are therefore likely driven mainly by the balance between HONO sources and the photolytic sink, whereas dilution effects appear to play only a minor role. The estimation of OH radical production from HONO and O$_3$ photolysis based on retrieved HONO near-surface concentrations and calculated photolysis rates indicate that in the 0–200 m altitude range, HONO is by far the largest source of OH radicals in winter as well as in the early morning at all seasons, while the contribution of O$_3$ dominates in summer from mid-morning until mid-afternoon.

1 Introduction

Since the late 1970s, nitrous acid (HONO) has been identified as a key chemical species in the troposphere, especially through its photolysis which leads to the formation of the hydroxyl radical OH (Perner and Platt, 1979). OH is known as the major oxidant (“detergent”) of the atmosphere responsible for the degradation of most pollutants. It contributes also to the formation of ozone and PANs (peroxyacyl nitrates)
causing the so-called “photochemical smog” in polluted regions, as well as to the formation of aerosol particles from the oxidation of volatile organic compounds (VOCs). The photochemistry of HONO has been and is still extensively discussed in the literature (see e.g., Sörgel et al., 2011a; Li et al., 2012; Elshorbany et al., 2012). The heterogeneous conversion of nitrogen dioxide (NO\(_2\)) on wet organic and inorganic ground surfaces (soil, buildings, vegetation, and aerosols) is believed to be a major source of HONO, and very probably its main source during the night (Wojtal et al., 2011 and references therein):

\[
2\text{NO}_2 + \text{H}_2\text{O} + \text{surface} \rightarrow \text{HONO} + \text{HNO}_3 \quad (R1)
\]

Recent field studies and laboratory measurements have identified other heterogeneous daytime sources like photosensitized reduction of NO\(_2\) on organic surfaces (George et al., 2005; Stemmler et al., 2006) and the photolysis of adsorbed nitric acid/nitrate at UV wavelengths (Zhou et al., 2003). Su et al. (2011) also showed that soil, through nitrite-producing microbes, can release important HONO amounts. Other HONO sources are direct emissions from combustion processes and the following gas-phase reaction:

\[
\text{NO} + \text{OH} + \text{M} \rightarrow \text{HONO} + \text{M} \quad (R2)
\]

Reaction (R2) operates only during daytime, when the OH and NO concentrations are high. HONO sinks include dry deposition during nighttime, and photolysis (Reaction R3) during daytime, at a rate close to \(10^{-3}\) s\(^{-1}\) around noon (see Sect. 3.3):

\[
\text{HONO} + h\nu(\lambda < 400\text{nm}) \rightarrow \text{OH} + \text{NO} \quad (R3)
\]

\[
\text{HONO} + \text{OH} \rightarrow \text{H}_2\text{O} + \text{NO}_2 \quad (R4)
\]

The reaction of HONO with OH (Reaction R4) is comparatively very slow. The rapid photolysis of HONO accumulated during the night is the main source of OH radicals in early morning when other radical sources, i.e., the photolysis of ozone and carbonyls, are still weak. It should be noted that recent measurements in the Los Angeles Basin have suggested that nitryl chloride (ClNO\(_2\)) can be, together with HONO, an important source of radicals in the morning in urban environments (Young et al., 2012). This study also showed that vertical gradients of radical precursors should be taken into account in radical budgets, especially in case of HONO.

Despite the numerous field campaigns and laboratory experiments conducted during the last three decades, the main HONO formation mechanisms are still not fully characterized, and their relative contributions to the observed HONO concentrations are not well quantified. Model simulations accounting only for anthropogenic emissions and the known gas phase formation through Reaction (R2) generally largely underestimate the measured daytime HONO levels, with possibly important consequences for the prediction of oxidants (OH, O\(_3\), PANs) (e.g., Kleffmann et al., 2005; Sörgel et al., 2011b). Consequently, the largely unknown HONO daytime source can have a significant impact on air quality and chemistry-climate modeling (Elshorbany et al., 2012 and references therein).

So far, HONO has been measured mainly using the long-path DOAS (Differential Optical Absorption Spectroscopy) and in-situ LOPAP-like (Long-Path Absorption Photometer) techniques. LOPAP is a wet chemical technique based on the dissolution of HONO in the liquid phase as nitrite (NO\(_2^-\)) followed by its detection as an azo dye (compound bearing the \(R - N = N - R'\) functional group) with a long-path absorption photometer (Heland et al., 2001; Kleffmann et al., 2002). The LOPAP instruments can generally be operated only for a limited period of time, from a few weeks to a couple of months, due to instrumental and logistics issues. Long-path DOAS is an active (i.e. using an artificial light source) DOAS technique consisting of the measurement of the trace gas concentration integrated along a light path of several hundred metres to a few kilometres between the light source and the spectrometer (Hönninger et al., 2004; Platt and Stutz, 2008). The first detection of HONO by long-path DOAS was made over the Los Angeles air basin in the late 1970s (Perner and Platt, 1979). Both long-path DOAS and LOPAP show a high sensitivity to HONO and have the advantage to be independent of daylight, enabling nighttime measurements.

Here we present four years of ground-based Multi-Axis (MAX-) DOAS observations of HONO and its main precursor NO\(_2\) and aerosols in the Beijing area from July 2008 till December 2012. It is the first time that measurements of HONO in or in the vicinity of a megacity are reported over such a long time period, allowing investigation of the seasonal variation of this species in urban conditions. MAX-DOAS is a passive DOAS technique based on measurements of scattered sunlight at zenith and at different elevation angles towards the horizon (the so-called off-axis geometry), increasing therefore the sensitivity to absorbers present close to the ground compared to the zenith scattered sunlight technique (Hönninger et al., 2004; Platt and Stutz, 2008). Due to the use of daylight and the need to minimise the contribution of the stratosphere for absorbers with strong stratospheric concentration like NO\(_2\) here, our MAX-DOAS observations are performed from \(\sim 85^\circ\) SZA (solar zenith angle) sunrise to \(85^\circ\) SZA sunset with a time resolution of \(\sim 15\) min (time needed for a complete MAX-DOAS scan). The instrumental setup including data transfer is fully automated, allowing continuous daily operation throughout the year. Moreover, by applying appropriate inversion methods like the Optimal Estimation (OEM; Rodgers, 2000), some information on the vertical distribution of the target trace gases can be retrieved in addition to the vertical column density (e.g., Hendrick et al., 2004; Hönninger et al., 2004; Wittrock et al., 2004; Friess et al., 2006; Clémer et al., 2010; Vlemmix et al., 2011). It should be noted that altitude-resolved measurements of trace gases are also possible with long-path DOAS.
or in-situ techniques, generally with a better vertical resolution and signal-to-noise ratio than MAX-DOAS, but these require more sophisticated instrumental set up like, for example, placing retro-reflectors or in-situ instruments on different floors of a building (e.g. Stutz et al., 2002; Wang et al., 2006; Wong et al., 2012; Villena et al., 2011).

In the present study, MAX-DOAS observations of HONO, NO$_2$, and aerosols have been performed from July 2008 to April 2009 in the Beijing city centre (39.98° N, 116.38° E) and from March 2010 until December 2012 at the suburban site of Xianghe (39.75° N, 116.96° E) located about 60 km east of Beijing. From these datasets, the diurnal and seasonal variations of the HONO and NO$_2$ vertical column densities (VCDs) and near-surface concentrations and aerosol optical depths (AODs) in the Beijing area are investigated. The OH production from HONO is also estimated based on the retrieved HONO concentrations and calculated photolysis rates. In Sect. 2, the MAX-DOAS measurements of HONO, NO$_2$, and aerosols are introduced, including a description of the instrumental set up, DOAS analysis settings, and vertical profile retrievals. HONO, NO$_2$, and AOD retrievals have been also verified through comparisons with correlative data. Section 3 presents the results: the seasonal variation of daytime HONO and NO$_2$ VCDs and near-surface concentrations and AODs, their diurnal variation and an estimation of the OH production from HONO and ozone. Concluding remarks are given in the last section.

2 MAX-DOAS measurements

2.1 Instrumental set up

The MAX-DOAS instrument used in this study has been extensively described in Clémer et al. (2010). It is a dual-channel system composed of two grating spectrometers covering the UV and visible wavelength ranges (300–390 nm and 400–720 nm, respectively). The output of both spectrometers is connected to cooled CCD detectors. The spectrometers and detectors are mounted inside a thermo-regulated box in order to minimise thermal stress on optical and mechanical parts. The instrument function is close to a Gaussian with a full width at half maximum (FWHM) of 0.4 nm and 0.9 nm for the UV and visible channels, respectively. Scattered light is collected at various elevation and azimuth angles by an optical head mounted on a commercial sun tracker (INTRA, Brusag) and the light is guided to the two spectrometers through optical fibres.

The instrument, which was designed and assembled at BIRA-IASB in Brussels, was installed during the July 2008–April 2009 period on the roof of the Institute of Atmospheric Physics (IAP) of the Chinese Academy of Sciences located in the Beijing city centre (39.98° N, 116.38° E). Then, it was moved to the suburban site of Xianghe (39.75° N, 116.96° E) located about 60 km east of Beijing where it has been operating continuously from March 2010 until now. At both locations, the azimuthal scan option was not activated and the telescope points towards a fixed azimuth direction (north). A full MAX-DOAS scan requires ~15 min and comprises the following 9 elevation angles: 2°, 4°, 6°, 8°, 10°, 12°, 15°, 30°, and 90° (zenith).

2.2 DOAS analysis

The measured scattered light spectra are analysed using the spectral fitting software suite QDOAS developed at BIRA-IASB (http://uv-vis.aeronomie.be/software/QDOAS/). The principle of the DOAS technique is to separate the absorption of molecular species which usually display narrow features from a broadband background resulting mainly from Mie and Rayleigh scattering and instrumental effects (Platt and Stutz, 2008). The direct product of the DOAS spectral fitting method is the differential slant column density (DSCD) which is the concentration of a given absorber integrated along the effective light path relative to the amount of the same absorber in a measured reference spectrum. For profile retrieval in the troposphere, it is a common way to select the zenith measurement of a MAX-DOAS scan as the reference for the off-axis DSCDs of the same scan in order to minimise the stratospheric signal (Clémer et al., 2010; Peters et al., 2012). This is particularly important for NO$_2$ which displays a significant concentration in the stratosphere.

HONO DSCDs are retrieved in the 337–375 nm wavelength range, taking into account the spectral signature of NO$_2$ at 220 and 296 K (Vandaele et al., 1998), O$_3$ at 218 and 243 K (Brion et al., 2004), O$_4$ (Hermans et al., 2003), BrO at 223 K (Fleischmann et al., 2004), HCHO at 293 K (Meller and Moortgat, 2000), and the filling-in of the solar Fraunhofer bands by the Ring effect (Grainger and Ring, 1962). The HONO absorption cross-sections at 296 K are obtained from Stutz et al. (2000). A fifth-order polynomial is used to fit the low frequency spectral structure due to molecular and Mie scattering. An example of DOAS fit for HONO is presented in Fig. 1.

In the case of NO$_2$, the 425–490 nm fitting window is used and, in addition to the NO$_2$ cross-sections at 220 and 296 K (Vandaele et al., 1998), the following trace gas cross-sections are taken into account in the DOAS analysis: O$_3$ at 241 K (Burrows et al., 1999), O$_4$ (Hermans et al., 2003), and H$_2$O (Harder and Brault, 1997). A Ring spectrum and a third-order polynomial closure term are also included. An example of DOAS fit for NO$_2$ is also shown in Fig. 1.

The O$_4$ DSCDs needed for the aerosol extinction profile retrieval (see Sect. 2.3) are retrieved in the UV and visible regions (338–370 nm and 425–490 nm, respectively) using the O$_4$ cross-sections from Hermans et al. (2003). The other DOAS settings are described in Clémer et al. (2010).

### 2.3 HONO, NO$_2$, and aerosol profile retrievals

HONO and NO$_2$ vertical profiles can be retrieved for each MAX-DOAS scan by applying an inversion algorithm to the corresponding sets of DSCDs measured at the different elevation angles. This profiling technique is based on the fact that the mean scattering height rises into the atmosphere with the increase of the elevation angle and probes the layers where the tropospheric absorber is present. So, each measured DSCD of a MAX-DOAS scan is representative of the absorber concentration in a given altitude range and therefore the observed DSCD variation as a function of the elevation angle depends on the vertical distribution of the absorber. In this study, we used the bePRO inversion algorithm developed at BIRA-IASB (Clémer et al., 2010). It is based on the Optimal Estimation Method (OEM; Rodgers, 2000) and uses a two-step approach. First, the aerosol extinction vertical profiles are retrieved separately at 360 and 477 nm for each MAX-DOAS scan from the corresponding measured O$_4$ DSCDs. The principle of this retrieval is the following: since the O$_4$ vertical profile is well-known and nearly constant (it varies with the square of the O$_2$ monomer concentration), O$_4$ DSCD measurements can provide information on the vertical distribution of aerosols (Wagner et al., 2004; Friess et al., 2006). This first step is required since the light path length through the atmosphere (and thus the measured HONO or NO$_2$ DSCD) strongly depends on the aerosols and therefore a good estimate of the vertical distribution of the aerosols is needed to perform accurate HONO and NO$_2$ profile retrievals. Further details regarding our aerosol retrieval (aerosol optical depth (AOD) and extinction coefficient), including the corresponding bePRO settings, are extensively described in Clémer et al. (2010). The only difference with the latter study is the use of two separate wavelengths (360 nm and 477 nm) instead of four (360, 477, 577, and 630 nm). In the second step, the bePRO algorithm is applied to the measured HONO and NO$_2$ DSCDs in order to retrieve vertical profiles of these trace gas species. In the OEM, the weighting function matrix ($\mathbf{K}$) and the a priori profile $x_a$ are two important retrieval parameters. $\mathbf{K}$ expresses the sensitivity of the measurements (DSCDs) to changes in the trace gas profile and it is calculated using the linearized discrete ordinate radiative transfer model (LIDORT; Spurr, 2008) as forward model. This code includes an analytical calculation of the weighting functions allowing for near real-time automated retrievals without the need of pre-calculated look-up tables. Since the present retrieval problem is ill-conditioned (no unique solution for the trace gas or aerosol extinction vertical profile due to the too small information content of fitted DSCDs from one MAX-DOAS scan), a priori constraints are needed to reject unrealistic solutions and to stabilise the inversion. For HONO and NO$_2$ vertical profile retrievals, exponentially decreasing a priori profiles have been used with a fixed scaling height of 0.5 km according to the following expression:

$$x_a(z) = \frac{\text{VCD}_a}{\text{SH}} e^{-\frac{z}{\text{SH}}}$$

where $x_a(z)$ is the a priori profile (HONO or NO$_2$ concentration as a function of the altitude $z$), SH is the scaling height (fixed to 0.5 km) and VCD$_a$ is the a priori vertical column density of HONO or NO$_2$. For each scan, VCD$_a$ is derived using the geometrical approximation, i.e. the HONO or NO$_2$ layer is assumed to be located below the scattering altitude at 30$^\circ$ Elevation, so that tropospheric HONO or NO$_2$ VCDs can be derived by applying a geometrical AMF to measured DSCDs at 30$^\circ$ Elevation (Hönnninger et al., 2004; Brinksma et al., 2008).

The other important retrieval parameter settings, which are the a priori and measurement uncertainty covariance matrices ($\mathbf{S}_a$ and $\mathbf{S}_v$, respectively), have been constructed as in Clémer et al. (2010). Profile retrievals have been performed at the following wavelengths: 354 nm for HONO and 460 nm for NO$_2$. The pressure and temperature profiles were taken from the US Standard Atmosphere and the retrieval grid was chosen as in Clémer et al. (2010): ten layers of 200 m thickness between 0 and 2 km, two layers of 500 m between 2 and 3 km and 1 layer between 3 and 4 km.
Examples of HONO, NO$_2$, and aerosol extinction coefficient profile retrievals for winter conditions are presented in Figs. 2, 3, and 4, respectively. The examination of the averaging kernels, which give information on the sensitivity of the retrievals to the vertical distribution, shows that the HONO and aerosols inversions are mostly sensitive close to the surface (0–200 m layer) and to the overhead column above 200 m. In the case of NO$_2$, three layers can be distinguished: 0–200 m, 200–400 m, and the column above 400 m. It should be noted that a similar vertical sensitivity is obtained for summer conditions. Since our study is mainly focused on HONO, we decided to investigate the HONO and NO$_2$ concentrations in the 0–200 m layer as well as the vertical column densities of these species. The retrieval of both columns and near-surface concentrations is the main strength of the MAX-DOAS technique: it helps to distinguish between photochemical and vertical transport influences on the diurnal cycle of HONO and NO$_2$ given that columns are less sensitive than concentrations to the growth of the boundary layer. Regarding the information content, it should be noted that the number of independent pieces of information, also called degrees of freedom for signal (DOFS) and given by the trace of the matrix $A$ (Rodgers, 2000), is generally larger for NO$_2$ than for HONO (2.7 and 1.8 in the examples shown in Figs. 2 and 3). This is due to the fact that the NO$_2$ absorption strength is larger by more than one order of magnitude than the HONO one, leading to a significantly higher sensitivity of the MAX-DOAS observations to NO$_2$.

From the error budgets presented in Figs. 2, 3, and 4, the contribution of the smoothing error, which represents the difference between the retrieved profile and the true profile due to vertical smoothing by the retrieval algorithm (Rodgers, 2000), is seen to be significantly larger than the noise (DOAS fit) error, except in the lowest layers. The sum of smoothing and noise errors on the HONO volume mixing ratio (VMR)
in the 0–200 m layer and on the HONO vertical columns amount on average to 19% and 8%, respectively at Beijing and to 23% and 10% at Xianghe. The corresponding values for NO$_2$ are 4% and 3%, respectively at Beijing and 8% and 3% at Xianghe. One of the main forward model error sources in HONO and NO$_2$ profile retrievals is the uncertainty on the retrieved aerosol extinction profiles in step 1. If we combine the smoothing and noise errors on the retrieved aerosol vertical profile (see Fig. 4) to a systematic error of 20% on O$_4$ DSCDs (Clémer et al., 2010; Wagner et al., 2009), the corresponding impacts on the HONO and NO$_2$ retrievals are in the 18–25% and 5–8% ranges for surface concentrations and VCDs, respectively. The uncertainty related to the choice of the a priori profile for the HONO and NO$_2$ retrievals has been estimated by varying the scaling height (SH; see Eq. 1) defining the a priori profile, more precisely, by adopting a value of either 0.5 km (standard retrieval) or 1 km. At Beijing, using a SH value of 1 km instead of 0.5 km leads to the following average changes on the retrieved quantities: $-7$ and $+10\%$ on the HONO and NO$_2$ near-surface concentrations, respectively, and $+20$ and $+10\%$ on the HONO and NO$_2$ vertical columns, respectively. The corresponding changes for Xianghe are $+11$ and $+14\%$ (HONO and NO$_2$ near-surface concentrations) and $+23$ and $+10\%$ (HONO and NO$_2$ vertical columns). Total uncertainties are estimated by combining the above error sources to the systematic uncertainty on the HONO and NO$_2$ cross-sections (5% and 3%, respectively, according to Stutz et al., 2000 and Vandeaele et al., 1998). The error budget on HONO and NO$_2$ near-surface concentrations and vertical column densities is presented in Table 1.

It is known that clouds and aerosols might bias the MAX-DOAS trace gas retrieval (Wagner et al., 2004; Friess et al., 2006). Instead of explicitly applying a cloud filtering approach, HONO, NO$_2$, and aerosol profile retrievals have been quality-checked for each MAX-DOAS scan by comparing the measured DSCDs to those calculated using the retrieved profiles (see examples of retrieval fit results in Figs. 2, 3, and 4 for HONO, NO$_2$, and aerosols, respectively). In practice, the selection of good profile retrievals is based on the following criteria: (1) residual (RMS) of the retrieval fit smaller than an empirically derived threshold value ($3.5 \times 10^{14}$ molec cm$^{-2}$ for HONO and $2.4 \times 10^{16}$ molec cm$^{-2}$ for NO$_2$), (2) DOFS larger than 0.7 meaning that the information comes mainly from the measurements and not from the a priori profile, (3) scans with bad O$_4$ fit results (RMS of the fit larger than 30% of the mean O$_4$ DSCD of the scan), which can be obtained, e.g. for changing aerosol loading or/and cloud conditions during a scan, are rejected, and (4) scans with very large AOD values (> 6) are also rejected given the significantly larger uncertainties on the trace gas retrievals in such conditions. Using these four criteria, about 35% of the scans are rejected at both stations.

### 2.4 Verification of the HONO, NO$_2$ and aerosol retrievals

The NO$_2$ and aerosol retrievals have been evaluated through comparison with correlative observations. In the case of NO$_2$, the VCDs retrieved in the Beijing city centre have been compared to MAX-DOAS measurements performed by Ma et al. (2013) at the China Meteorological Administration (39.95° N, 116.32° E) located at about 10 km southwest of the Institute of Atmospheric Physics where our MAX-DOAS spectrometer was installed. It is important to note that both instruments were pointing towards the same direction (North) and that Ma et al. (2013) have used the simple geometrical approximation to derive the NO$_2$ VCDs (no Optimal Estimation step such as in the present study). Figure 5 shows the comparison of seasonally averaged diurnal variations of the tropospheric NO$_2$ VCDs for the period August 2008 to April 2009. As can be seen, a very good agreement is obtained, with both MAX-DOAS datasets displaying very similar diurnal variation in both shape and absolute values. In fall and summer, however, our retrieved VCDs are notably noisier than in Ma et al. (2013). It is likely related to the smaller number of available retrievals during these seasons, due to the more strict scan selection criteria imposed in the OEM-based method (see Sect. 2.3) compared to the Ma et al. (2013) approach. Regarding aerosols, AODs at 360 nm retrieved at Beijing and Xianghe have been compared to correlative data from co-located CIMEL sunphotometers of the AERONET network (http://aeronet.gsfc.nasa.gov). As

shown in Fig. 6, a good consistency is found between MAX-DOAS and CIMEL instruments at both sites, with correlation coefficients and slopes very close to 1, in agreement with Clémer et al. (2010). These results indicate that the first step of our OEM-based trace gas retrieval, i.e. the aerosol profiling, is robust and reliable.

A thorough validation of HONO retrievals such as those carried out for NO\(_2\) and aerosols is currently not possible due to the lack of correlative datasets at both stations. However, as in Li et al. (2012), MAX-DOAS HONO surface concentrations have been compared to other existing measurements made in or in the vicinity of big cities in East Asia. As can be seen in Table 2, Beijing and Xianghe values are at the low end of existing measurements in spring/summer while they are comprised between the concentrations measured at Shanghai and Xinken (Pearl River Delta region) data in fall/winter. These results show that our MAX-DOAS HONO retrievals at Beijing and Xianghe are reasonably consistent with other existing measurements in East Asia, giving us confidence on the reliability of our HONO datasets. This compilation of HONO measurements also further confirms that the Pearl River Delta region is among the most important HONO hot spots in the world.

Fig. 5. Comparison of seasonally averaged tropospheric NO\(_2\) VCD diurnal variations from MAX-DOAS measurements performed at the Institute of Atmospheric Physics (present study) and at the China Meteorological Administration (Ma et al., 2013) in the Beijing city centre. The period covered by the observations is August 2008–April 2009. Ma et al. (2013) is taken as reference for the calculation of relative differences. The calculated mean biases are: +3 ± 9 % in spring, +3 ± 20 % in summer, +4 ± 12 % in fall, and −2 ± 6 % in winter.

Fig. 6. Scatter plots of the AODs at 360 nm retrieved from MAX-DOAS and sunphotometer measurements at Beijing (left plot, August 2008–April 2009) and Xianghe (right plot, March 2010–December 2012). The linear regressions appear in red and the green dashed lines correspond to the 1 : 1 lines.

3 Results and discussion

3.1 Seasonal variation of daytime HONO, NO\(_2\), and aerosols

Time-series of daytime (local noon) HONO and NO\(_2\) surface concentration and VCD as well as AOD (360 nm) monthly means are presented in Fig. 7. A marked seasonality of the HONO surface concentration and VCD is observed at both stations, with a maximum in late fall/winter and a
minimum in summer. The HONO surface concentration (0–200 m layer) ranges between ~0.1 and 0.8 ppb in Beijing and between ~0.03 and 0.7 ppb in Xianghe. These values are consistent with published daytime surface measurements of HONO performed in or in the vicinity of big cities and ranging from 0.05 to 2 ppb (Li et al., 2012), the lowest and highest values having been observed in Tokyo (Kanaya et al., 2007) and in Guangzhou City, South China (Qin et al., 2009), respectively (see also Table 2). From Fig. 7, it is found that the HONO seasonal variation follows well the seasonality of NO$_2$ which is believed to be its main precursor. The late fall/winter maximum is a well-known feature of NO$_2$ columns over industrialized areas at mid-latitudes and in particular over Northeastern China (Richter et al., 2005) and is mainly attributed to the longer photochemical lifetimes caused by the winter depletion of OH radical levels (Stavrakou et al., 2013). Domestic heating also contributes to the late fall/winter maximum, but its role is minor due to the dominance of other NO$_x$ sources in Eastern China (Zhang et al., 2007). The HONO seasonality is the result of both enhanced production in winter (due to the NO$_2$ maximum) and more efficient photolysis in summer. Furthermore, the boundary layer height (BLH) is higher in summer than in winter, about 3 and 1 km in summer and winter, respectively, according to ECMWF ERA-Interim data, leading to a larger dilution of HONO in summer and therefore to lower concentrations close to the surface. This effect seems minor, however, since the seasonal cycle of HONO VCD has an only slightly lower relative amplitude (peak-to-trough ratio between 5 and 10) compared to the near-surface concentration (ratio around 10). Figure 7 also shows that the AOD has a distinct seasonality with a maximum in spring/summer and a minimum in winter. Such a seasonal variation of the AOD over Beijing was also reported by Yu et al. (2009a) using AERONET observations. It can be mainly attributed to particles emitted from massive agricultural fires in the region surrounding Beijing during the May–July period with a peak in June (Xia et al., 2013) as well as to long-range transport of dust particles during spring/summer (Yu et al., 2009a).

Related to Fig. 7, it should be also noted that the corresponding monthly mean DOFS range between 2.0 and 3.0 for NO$_2$, and 1.8 and 2.2 for aerosols, indicating that the retrieved surface concentration or extinction coefficient is independent from the corresponding VCD or AOD. It is also the case for HONO during the late fall/winter/early spring period with a DOFS around 1.8–2.0. In summer, the DOFS decreases to values around 1.5, suggesting that the surface concentration is to some extent not independent from the retrieved VCD and a priori profile shape. The number of days used for the calculation of monthly means exhibits a similar seasonality with a maximum in fall/winter/early spring (~25–30 days) and a minimum in summer (~15 days) due to the low daytime HONO amounts observed during this period making the OEM-based retrieval less stable and leading therefore to a larger number of rejected scans.

The HONO, NO$_2$, and aerosol seasonal variations at both stations are further illustrated in Fig. 8 where the monthly near-surface concentrations, VCDs, and AODs around local noon have been averaged over the whole measurement period. The HONO concentrations and columns are found to be generally larger at Beijing than at Xianghe, as a result of the larger NO$_2$ concentrations observed in the Beijing city centre (Figs. 7 and 8). The largest difference between the sites concerns the 90th percentile of HONO surface concentrations (Fig. 8) which can reach up to 2 ppb at Beijing in winter while the corresponding values do not exceed 1.25 ppb for the same period at Xianghe. The heterogeneous conversion of NO$_2$ into HONO appears to be very probably the dominant source of HONO at both sites and especially in Beijing, given the high correlation coefficient found between HONO and NO$_2$ near-surface concentrations ($R_{\text{HONO/NO}_2}$) and between HONO concentration and the
Fig. 8. Seasonal variation of the HONO and NO₂ surface concentration and vertical column density (VCD) and AOD at 360 nm at Beijing (left plots) and Xianghe (right plots). Data correspond to monthly averages over the time interval of ±2 h around local noon. The cross symbol and the lower (upper) error bars represent the median and the 10th (90th) percentiles of the data, respectively.

aerosol extinction coefficient ($R_{HONO/AERO}$) retrieved in the 0–200 m layer. Figure 9 shows that $R_{HONO/NO2}$ lies in the range 0.7–0.9 at Beijing and 0.5–0.8 at Xianghe, while the corresponding $R_{HONO/AERO}$ values are comprised between 0.60 and 0.95 and between 0.55 and 0.85, respectively. It should be noted that a strong correlation is also obtained between NO₂ and aerosols in the 0–200 m layer with correlation coefficients ranging between 0.6 and 0.9 at both stations. Similar correlation coefficient values are obtained between integrated concentrations, i.e., between HONO and NO₂ VCDs, between HONO VCD and retrieved AOD, and between NO₂ VCD and retrieved AODs, suggesting that the high correlation obtained for surface concentrations is not due to changes resulting from the variation of the boundary layer height. As can be seen from Fig. 10, the high correlations found between HONO, NO₂, and aerosols are driven at both stations by day-to-day changes: within one month (summer or winter), the short-term variations of the daily means exhibit the same patterns with peaks and troughs on the same days for both trace gases and aerosols. Although a strong correlation is expected between NO₂ and HONO, since NO₂ is recognised as the main precursor of HONO, the same is not true for the correlation between NO₂ and aerosols. Therefore, the high correlation is, more than likely, mainly of meteorological origin, given the relative similarity in the spatial distribution of aerosols and NO₂, which both have a strong anthropogenic component. For HONO and aerosols, the high correlation might be further enhanced by the expected role of aerosols as mediator in the heterogeneous conversion of NO₂ to HONO. Due to the high concentrations of PM₁₀ and PM₂.₅ usually observed in the Beijing area, heterogeneous reactions on aerosols have been...
and the season-averaged concentrations, vertical columns and ratios are summarised in Tables 3 and 4. The scaling of HONO to NO$_2$ or NO$_x$ is often used to make the link between HONO and its possible sources, i.e., as an indicator of the efficiency of the conversion of NO$_2$ into HONO (e.g., Sörgel et al., 2011a; Wojtal et al., 2011; Li et al., 2012). The HONO/NO$_2$ ratio values are usually sorted into the three following regimes (Wojtal et al., 2011 and references therein): direct emission (HONO/NO$_2$ less than 0.01) and surface sources in low and high relative humidity environments (HONO/NO$_2$ in the 0.01–0.03 and 0.03–0.1 ranges, respectively). It should be noted that HONO/NO$_2$ ratio values up to 0.30 have been derived from nighttime long-path DOAS measurements in Kathmandu, Nepal by Yu et al. (2009b) and were explained by high pollution and relative humidity and low inversion layer. The monthly averaged HONO/NO$_2$ ratio observed in the 0–200 m layer is comprised on average between 0.007 and 0.028 at both sites (Fig. 9). Although there are significant differences (up to a factor of 2) between the near-surface concentrations ratios observed at Beijing and Xianghe, the VCD ratios are remarkably similar at both sites, and show only little seasonal variations, with values varying between 0.008 in summer and 0.013 in fall and winter (see Table 4 and also Fig. 9). The summertime minimum is consistent with the higher photolytic sink in that season. Higher ratio values are obtained in the 0–200 m layer, by a factor ranging between 1.5 and 2, due to the shorter HONO lifetime and hence the stronger vertical gradients for HONO compared to NO$_2$ (see e.g. Figs. 2 and 3). Although the photolytic loss of HONO is likely an important driver of these daytime HONO/NO$_2$ ratios, differences between the seasonal variations of the near-surface concentration ratios at both sites are observed (see Fig. 9), suggesting that other processes can play a significant role. These could be, e.g., differences in vertical mixing or effects of horizontal transport of NO$_2$, especially during the winter when lifetimes are long. The 90th percentile of the monthly-averaged near-surface HONO/NO$_2$ ratios indicates that this ratio can reach values of up to about 0.05 at both sites (Fig. 9). The mean and 90th percentile values reported here are consistent with those measured around local noon in big cities and ranging from 0.003 to 0.075 (Li et al., 2012; Elshorbany et al., 2012, and references therein).

**3.2 Diurnal variation of HONO and NO$_2$**

Since the MAX-DOAS instrument operates continuously from about 85$^\circ$ SZA sunrise to 85$^\circ$ SZA sunset with a time resolution of $\sim$ 15 min, the diurnal variation of HONO and NO$_2$ surface concentrations and VCDs can be thoroughly investigated throughout the year at both stations. Figure 11 presents the diurnal variations of HONO and NO$_2$ surface concentrations and HONO/NO$_2$ ratios (VMR/VMR) observed at Beijing and Xianghe. Measurements have been averaged per season using 1 h bins.
Table 3. Mean HONO near-surface concentration (VMR in ppb unit) and vertical column density (VCD in $10^{15}$ molec cm$^{-2}$ units) around local noon ($\pm 2$ h) at Beijing and Xianghe. The 10th and 90th percentiles of the data are also given.

</table>

The diurnal cycle of NO$_2$ reflects the balance between anthropogenic emissions and photochemical sinks. In fall/winter, when photochemical activity is weak, accumulation of NO$_2$ results in a continuous increase of its concentrations during the day, whereas in spring/summer, the diurnal cycle is relatively flat. The diurnal cycle of the HONO concentration in the 0–200 m layer exhibits a maximum in the early morning (1.3–1.6 ppb and 0.7–1.0 ppb at Beijing and Xianghe, respectively) due to the nighttime build-up, followed by a decrease. This decrease continues throughout the day at both stations in fall/winter, while in spring/summer the HONO concentration remains relatively constant from local noon until about 16:00, after which time HONO increases slightly until sunset. This diurnal cycle shape is similar to the cycle observed in several field campaigns (Qin et al., 2009; Li et al., 2012; Elshorbany et al., 2012 and references therein). The morning decrease can be attributed to the increasing HONO photolysis rates and vertical mixing, while the HONO increase in the late afternoon can be caused by the progressive absence of photolytic loss and the decrease of the boundary layer height. However, since the HONO VCD has a very similar diurnal cycle (see Fig. 12), the surface concentration variation during the day is therefore not driven by dilution effects. This is consistent with the study of Qin et al. (2009) which indicated a higher correlation between HONO and NO$_2$ at Guangzhou than between HONO and CO, the latter being used as a tracer for the transport processes.

As shown in Figs. 11 and 12, the HONO/NO$_2$ ratio (VMR/VMR and VCD/VCD) has a marked diurnal cycle at both stations with, as for HONO, a maximum in the early morning (ratio values up to about 0.05–0.08 in summer) and a decrease during daytime to values around 0.01–0.02. It should be noted that this diurnal cycle, with the absence of a significant increase of the HONO/NO$_2$ ratio around local noon, is very similar to the one derived by Qin et al. (2009) from long-path DOAS observations in Guangzhou city.

The corresponding diurnal variations of the AOD are also presented in Fig. 12. There is no marked diurnal cycle, with values around 1–1.5 at both stations, except in Beijing in summer where the AOD increases during the morning, with a maximum value of 3 around 11:00.
3.3 Estimation of OH production from HONO

In order to evaluate the importance of HONO as a source of OH radicals, especially compared to the contribution of O$_3$ photolysis, the OH production from HONO has been calculated in the 0–200 m layer at both stations from the retrieved HONO concentrations and simulated photolysis rates $J$ (HONO). OH is formed from O$_3$ through the following reaction sequence:

\[ \text{O}_3 + h\nu (\lambda < 340\text{ nm}) \rightarrow \text{O}(^1\text{D}) + \text{O}_2 \]  
(R5)

\[ \text{O}(^1\text{D}) + \text{H}_2\text{O} \rightarrow 2\text{OH} \]  
(R6)

The corresponding OH production has been estimated from an assumed O$_3$ concentration fixed to 30 ppb, water vapour concentration from ECMWF (European Centre for Medium-Range Weather Forecasts) ERA-Interim re-analysis fields (http://www.ecmwf.int/research/era/do/get/index), and simulated photolysis rate $J$ (O$_3 \rightarrow \text{O}(^1\text{D}))$. Since the value of 30 ppb for O$_3$ is significantly smaller than the afternoon O$_3$ concentrations (up to 60 ppb) observed in summer (Lu et al., 2013; Wu et al., 2011), we tested the impact of using the diurnal cycle of O$_3$ measured by Chou et al. (2011) in the Beijing city centre during CAREBeijing-2006. Photolysis rates have been calculated using the TUV package including the SDISORT radiative transfer code (Madronich and Hocke, 1998). The effects of clouds are ignored, whereas attenuation by aerosols is estimated from the aerosol optical depths retrieved by MAX-DOAS at Beijing and Xianghe (see Sect. 2.3), assuming a single scattering albedo equal to 0.9 and an asymmetry parameter equal to 0.7. The albedo is set to 0.05, except over snow (0.5). Snow presence and ozone total columns are obtained from ECMWF ERA-Interim fields.

The calculated photolysis rates are presented in Fig. 15. The $J$ (HONO) values are consistent with those measured by Li et al. (2012) in the Pearl River Delta region in Southern China, and correspond to a noon photolytic lifetime of about 15–20 min, with little differences between the seasons. The diurnal cycles of OH production due to HONO and O$_3$ are depicted in Fig. 14. At both stations, the OH production from HONO in the 0–200 m layer exhibits a maximum...
in the morning, between 07:00 and 09:00 in spring/summer and between 08:00 and 11:00 in fall/winter. This maximum is larger at Beijing than at Xianghe, with e.g. winter values reaching 1.2 ppb h\(^{-1}\) and 0.7 ppb h\(^{-1}\), respectively, due to the generally larger HONO concentration observed in Beijing (Fig. 11). The shape of this diurnal cycle is similar to the one calculated by Sörgel et al. (2011b) from HONO measurements over a pine forest close to the industrial area of Huelva, southwestern Spain in fall. However, the maximum of OH production from HONO was significantly lower there (\(\sim 0.2\) ppb h\(^{-1}\)).

Comparison of the HONO and \(O_3\) contributions to OH production reveals that HONO is the main contributor in all seasons except summer, with relative HONO contributions larger than 70\% (more than 90\% in winter) around 12:00–13:00. In summer, the contribution of \(O_3\) dominates between 09:30 and 16:00 with a maximum of 70\% around 13:00–14:00. At Beijing, this feature is strengthened by considering the diurnal cycle of the ozone concentration measured by

Chou et al. (2011) with high afternoon ozone mixing ratios, and very low values in the early morning. In that case, the contribution of \(O_3\) to OH production reaches a maximum of 80\% in the early afternoon.

The seasonal variation of the HONO and \(O_3\) contributions at local noon is displayed in Fig. 15. It is largely explained by the seasonal cycle of ozone photolysis rates (Fig. 13) and H\(_2\)O concentrations, which both maximise in summer. These results show that near to the ground surface in urban areas, HONO is the main source of OH radicals in winter as well as in the early morning at all seasons, in agreement with our current knowledge of the HONO photochemistry (see e.g. Li et al., 2012 and references therein).
marked seasonality, with a maximum in late fall/winter and a minimum in summer. The strong link between HONO and NO$_2$ is further supported by the high correlation of HONO with NO$_2$ found throughout the year, with coefficients comprised in the 0.7–0.9 and 0.5–0.8 ranges at Beijing and Xianghe, respectively. Like NO$_2$, HONO is more abundant at Beijing than at Xianghe, with mean VMR ranging from ~0.1 to 0.8 ppb and from ~0.03 to 0.7 ppb, respectively. These values are found to be consistent with previously reported daytime HONO measurements in urban conditions. A strong role of NO$_2$ conversion to HONO at Beijing is suggested from the higher correlation coefficients between HONO and aerosol extinctions retrieved in the 0–200 m layer at Beijing (ranging from 0.60 to 0.95 instead of 0.55 to 0.85 at Xianghe).

The diurnal profiles of HONO surface concentration and vertical column show a maximum in the early morning (1.3–1.6 ppb/1.5–1.8 $\times$ 10$^{15}$ molec cm$^{-2}$ in Beijing and 0.7–1.0 ppb/0.9–1.1 $\times$ 10$^{15}$ molec cm$^{-2}$ in Xianghe) likely explained by the photolysis of the HONO accumulated during the night. The subsequent decrease (to about 0.1–0.4 ppb for the concentration and 0.1–0.6 $\times$ 10$^{15}$ molec cm$^{-2}$ for the vertical column around local noon) results mostly from a balance between HONO sources and the photolytic sink. Dilution effects appear to play only a minor role, given the observed similar diurnal cycle of the HONO vertical column, which is expected to be insensitive to vertical transport variations. The observed HONO/NO$_2$ ratio diurnal cycle is very similar at both Beijing and Xianghe with a maximum in the early morning (values up to 0.08) and subsequent decreases to values ranging between 0.01 and 0.02 around local noon.

The production of OH radicals from HONO and O$_3$ has been estimated from observed HONO near-surface concentrations and calculated photolysis rates. At both stations, HONO is found to be the main contributor to OH production in the 0–200 m layer, except in summer around local noon where the contribution of O$_3$ dominates. The diurnal cycle of the OH production from HONO exhibits a maximum in the morning between 07:00 and 11:00, depending on season, followed by a rapid decrease. This maximum is larger at Beijing than at Xianghe, especially in winter time where the OH production from HONO reaches ~1.2 ppb h$^{-1}$ and ~0.7 ppb h$^{-1}$, respectively.

To conclude, MAX-DOAS is shown to be a useful technique for long-term monitoring HONO near-surface concentrations and vertical column amounts in polluted areas. Multi-year data sets of HONO observations, such presented in this work, offer a better quantitative characterisation of HONO photochemistry and can provide additional constraints to modelling studies. For example, the diurnal and seasonal profiles of the HONO/NO$_2$ ratio derived in this study could be used in atmospheric models to constrain the rate of heterogeneous conversion of NO$_2$ to HONO, in order
to investigate the possible effects of this HONO source on the budget of oxidants.
