Abstract
Internal dry reforming of methane is envisaged as a possibility to reduce on capital and operation costs of biogas fuelled solid oxide fuel cells (SOFCs) system by using the CO$_2$ present in the biogas. Due to envisaged internal dry reforming, the requirement for biogas upgrading becomes obsolete, thereby simplifying the system complexity and increasing its technology readiness level. However, impurities prevailing in biogas such as H$_2$S have been reported in literature as one of the parameters which affect the internal reforming process in SOFCs. This research has been carried out to investigate the effects of H$_2$S on internal dry reforming of methane on nickel-scandia-stabilised zirconia (Ni-ScSZ) electrolyte supported SOFCs. Results showed that at 800°C and a CH$_4$:CO$_2$ ratio of 2:3, H$_2$S at concentrations as low as 0.125 ppm affects both the catalytic and electric performance of a SOFC. At 0.125 ppm H$_2$S concentration, the CH$_4$ reforming process is affected and it is reduced from over 95% to below 10% in 10 h. Therefore, future biogas SOFC cost reduction seems to become a trade-off between biogas upgrading for CO$_2$ removal and biogas cleaning of impurities to facilitate efficient internal dry reforming.

KEYWORDS
H$_2$S, Internal dry reforming, Ni-based catalyst, SOFC poisoning
## INTRODUCTION

Biogas is one of the most common energy carriers recovered from waste. It is mainly composed of CH$_4$ and CO$_2$. In the presence of heat and a catalyst, CH$_4$ reacts with CO$_2$ to form H$_2$ and CO which are potential SOFC fuels. SOFCs operate often with Ni-based anodes at temperatures between 600 and 1000°C. Ni can catalyse CH$_4$ and CO$_2$ reforming reaction at temperatures as low as 400°C. SOFCs are reported to be tolerant to CO-containing fuels. This provides an opportunity for internal reforming in SOFCs, since Ni is also a catalyst for CH$_4$ reforming. Hence, there is a possibility to use biogas as a fuel for SOFCs. However, there are still technical challenges such as carbon deposition, thermal stress and gas contaminant poisoning for direct biogas-fuelled SOFCs. Therefore, currently research is being directed to develop more efficient Ni-based catalysts for electro-catalytic reforming.

Possibilities of methane internal dry reforming in SOFCs were investigated by Goula et al. Authors observed that internal dry reforming is indeed feasible in SOFCs. However, full dry reforming is still a challenge especially if Ni-based SOFC anodes are used due to the risk of carbon deposition and nickel re-oxidation in the H$_2$-lean portions of the anode. The possibility for internal dry reforming can greatly reduce the overall system costs by 6% if external reformers can be eliminated from the system. Also, Schubert and Kusnezoff reported that direct internal reforming of SOFCs fuelled with biogas is preferred due to its foreseeable cost reduction in the overall plant investment. It is important to note that currently the major drawback of SOFC application in the energy sector is high upfront capital expenditures. Therefore, for small-scale systems, internal dry reforming could also reduce the overall system costs, which is critical especially for systems less than 10 kW capacity.

However, gas impurities are generally considered to be detrimental to the reforming process and general operation of the SOFC system. Among the impurities in the biogas, H$_2$S is considered as the most detrimental and thermodynamically stable gas at the common operating conditions of SOFCs. It is generally agreed that H$_2$S may have an influence on both the chemical and electro-chemical reaction on the Ni anodes. These effects can be potentially influenced by a number of parameters ranging from fuel composition to materials from which SOFC anodes are developed. In SOFCs, biogas dry reforming would be preferred to steam reforming since it is seen as a possible mechanism of cost and system complexity reduction. Moreover, small-scale SOFCs are being promoted by a number of companies and such system would be suitable for internal dry reforming if they are to be fuelled by biogas.

It has been reported that H$_2$S content in the gas as low as 2 ppm already has an effect on the internal SOFC steam reforming process. However, this effect could be different during dry reforming process in the presence of CO$_2$. Moreover, even with reformed gas, H$_2$S as low as 0.5 ppm has been reported to affect the electro-chemical performance of SOFCs at 750°C. Under syngas operation, nickel-gadolinium-doped ceria (Ni-GDC) anode material showed good performance as compared to other materials like nickel-yttria-stabilised zirconia (Ni-YSZ). Ni-GDC has been reported to have an enhanced tolerance of H$_2$S in the presence of hydrocarbon (H/C) fuels, and this is attributed to CeO$_2$ which enhances reforming and as well as H$_2$S tolerance. Also, addition of Cu to Ni anodes could stabilise the active surface of the anode by limiting the rate of carbon deposition. Therefore, the effect of H$_2$S on dry reforming could also be influenced by material composition of the anode.

Under steam reforming conditions, H$_2$S has been reported to have a larger effect on reforming activity than on the electro-chemical activity even at H$_2$S concentration of 2–4 ppm levels. This is also in agreement with Aravind et al. This could be due to the different reforming and electro-chemical sites within the cell. H$_2$S has been reported to decrease the rate of the water gas shift reaction. Therefore, the effect of H$_2$S on the performance of SOFCs generally depends on material composition of the anode and operating parameters such as temperature. H$_2$S effect on the catalytic performance of a catalyst varies depending on the material composition. Hence, in the presence of reforming gases, H$_2$S could have an effect on both chemical and electro-chemical process and this effect would vary depending on the specific operational conditions of the SOFC, its material composition and fuel gas composition.
The effect of H$_2$S on dry reforming was investigated by Shiratori et al.\textsuperscript{32} In their experiment, they used an electrolyte supported Ni-ScSZ cermet SOFC of $8 \times 8$ mm$^2$. A simulated biogas of CH$_4$/CO$_2$ = 1.5 at SOFC operating temperature of 1000°C was used at a current density of 200 mA cm$^{-2}$. Under these conditions, a 9% drop in voltage and 40% drop in reforming reaction rate was observed during poisoning of the cell by 1 ppm of H$_2$S. They observed that under these conditions, a concentration of 1 ppm H$_2$S is feasible during internal dry reforming. With real biogas, a constant voltage above 0.9 V was attained during the 50 h of operation with no observation of carbon deposition. Attempts to study the effect of H$_2$S on dry reforming by Xu et al.\textsuperscript{33} were hindered by carbon deposition; therefore, no results were yielded from the experiment. Johnson et al.\textsuperscript{22} studied the effect of H$_2$S on dry reforming under catalytic conditions. They found out that the effect of H$_2$S was more severe under steam reforming as compared to dry reforming. This is also re-affirmed by Lakshminarayanan et al.\textsuperscript{34} Also, it was reported that H$_2$S appears to increase the chances of carbon deposition.\textsuperscript{35} Table 1 represents H$_2$S tolerance for different anode materials with varying gas composition and experimental conditions from selected literature.

It is generally agreed that H$_2$S may have an effect on the dry reforming process depending on the type of catalysts and operating conditions.\textsuperscript{36,37} But detailed analysis is still required to investigate the H$_2$S concentration limit for SOFCs and the performance of the cell close to real operating conditions of normal-sized SOFCs. Therefore, this research has given focus on investigating the effects of H$_2$S on dry reforming under both current load and open-circuit voltage (OCV) operating conditions of SOFCs. To the authors knowledge, no attempt has been done to investigate the effects of H$_2$S on dry reforming under typical SOFC operating conditions (800–850°C) of relatively large surface area SOFC (close to real operating conditions of normal-sized SOFC) under current and OCV. Moreover, the boundary limit of H$_2$S concentration in fuel gas at a typical SOFC operational condition of 800–850°C with internal dry reforming has not been investigated.

2 \hspace{1em} MATERIALS AND METHOD

It is hypothesised that the effect of H$_2$S on dry reforming will vary depending on operating conditions. Hence, experiments were conducted under different operating conditions.

2.1 \hspace{1em} Experimental setup

Experiments have been conducted to evaluate the performance of a SOFC under dry reforming in the presence of H$_2$S at 800°C. The setup used is shown in Figure 1. In this experiment, commercial Ni-ScSZ electrolyte-supported cells with an active area of 81 cm$^2$ were used.

The gases were supplied from gas bottles. Composition and flow rate were varied using mass flow controllers (MFC) (Bronkhorst High-Tech BV). The inlet gas to the anode was trace heated to 130°C. Temperature of the oven was maintained by 4 electrical heaters controlled by the furnace control unit. The performance of the cell was analysed by Gammry FC-350. Outlet gas composition was analysed by micro gas chromatograph device. The anode outlet gas was dried using silica gel for analysis in Agilent 490 micro-GC columns (Molsieve 5A and PoraPLOT U). The cell temperature was measured by the k-type thermocouple (RS PRO, −50°C/+1200°C) closely placed at the anode side. The cells were placed between two ceramic blocks. To ensure gas tightness, mica (therm-iculite) sheets were placed in the anode side and in the cathode side. To enhance gas sealing, extra weights were added on the top of the block as represented in Figure 1. For further details of the set-up, the reader is referred to Saadabadi et al.\textsuperscript{45}

2.2 \hspace{1em} Experimental procedure

The cells were preheated by heating the furnace to 1000°C at a ramp rate of 50°C h$^{-1}$ with N$_2$ gas flowing at a rate of 1200 ml min$^{-1}$ to the anode and cathode. At 950°C, the NiO of the anode was reduced by feeding H$_2$ to the anode and simulated air (O$_2$ and N$_2$) to the cathode. During cell reduction, the concentration of H$_2$ gas was gradually increased from 2% to 100% in 4 h. The current-voltage measurements were carried out after the cell reduction procedure.

The cells were fed with CH$_4$, CO$_2$ and N$_2$ mixture with different compositions. H$_2$S injection was carried out by including H$_2$S in the gas mixtures which was in N$_2$ bottle. The concentration of H$_2$S in the fuel gas was varied by changing the flow from H$_2$S/N$_2$ (H$_2$S concentration of 50 ppm) bottle and compensating it with the flow from N$_2$ bottle to maintain a total of 1200 Nml min$^{-1}$. The ratio of CH$_4$:CO$_2$ in this experiment was 2:3. The ratio was chosen to have enough CO$_2$ which can suppress carbon deposition.\textsuperscript{46,47} After poisoning with H$_2$S, the cells were recovered using pure H$_2$ balanced with N$_2$ gas for 12 h.

To determine the effect of H$_2$S on dry reforming under current conditions using a Ni-ScSZ cell, a constant current of 2 A (250 A m$^{-2}$) was drawn from the cell using CH$_4$:CO$_2$ of 2:3 as fuel at 800°C. Starting with H$_2$S concentration of 0 ppm, the cell was poisoned with 0.125 ppm and the percentage of CH$_4$ reformed was...

monitored by samples analysed in the Agilent 490 micro-GC columns until the cut-off voltage of 0.6 V which was monitored by Gammry FC-350. The percentage of CH$_4$ reformed was calculated based on the carbon balance of outlet gas composition described in Saadabadi et al.\textsuperscript{45} The experiment was repeated by increasing the H$_2$S concentration to 0.5 ppm and 1 ppm. To determine the effect of H$_2$S on dry reforming under OCV conditions (purely dry conditions), the experimental conditions were maintained and the cell was poisoned by H$_2$S concentration of 0.125 ppm.

In order to determine the contribution of the cell material (catalyst) to the H$_2$S effects on reforming, the experiment was repeated using dummy cell mica (thermiculite) sheet. The effect of H$_2$S on reforming was evaluated at CH$_4$:CO$_2$ of 2:3 and at 800°C dummy cell temperature.

3 | RESULTS AND DISCUSSION

3.1 | Effect of H$_2$S on dry reforming on Ni-ScSZ under current

Using the Ni-ScSZ electrolyte-supported cell under a current of 2 A (250 A m$^{-2}$) at 800°C cell temperature and CH$_4$:CO$_2$ ratio of 2:3, it was observed that with no H$_2$S in the fuel gas (0 ppm), CH$_4$ reforming was more than 95%. If H$_2$S is gradually introduced in the gas, then the reforming efficiency (methane conversion) is reduced with time. Figure 2 shows how the concentration of H$_2$S in the gas affected both the cell voltage and the dry reforming process. With H$_2$S concentration of 0.125 ppm in the gas, there was no effect observed in the percentage of CH$_4$ reforming ($X_{\text{CH}_4}$) for 4 h. Also, the cell voltage was stable for the first 4 h. After 4 h,
CH$_4$ reforming started decreasing and a decrease in the cell voltage was observed. Between 4 and 10 h, a gradual decrease in the CH$_4$ reforming process and a decrease in cell voltage were observed. At the cut-off voltage of 0.6 V, CH$_4$ reforming process had decreased to 10%. The decrease in cell voltage can be attributed to the decrease in CH$_4$ reforming. These results suggested that the effect of H$_2$S is more pronounced at the reforming sites. A similar trend was observed when the H$_2$S concentration in the gas was increased to 0.5 ppm and 1 ppm but in a shorter period. This trend suggested that the decrease in cell voltage resulted from a reduction in H$_2$ and CO due to the reduced percentage of CH$_4$ reformed. It was reported that sites for reforming (catalytic sites) are different from electro-chemical sites. It seems that under dry reforming conditions, H$_2$S is adsorbed to the reforming sites. Similar to steam reforming, H$_2$S has an effect on the electro-chemical activity during dry reforming. These results have a good agreement with what was reported by Shiratori et al. They observed that H$_2$S can affect the reforming and electro-chemical performance of the cell, but the performance of the cell was tolerant to 1 ppm at 1000°C. However, our present research has revealed that 1 ppm of H$_2$S is not feasible in internal dry reforming at temperatures of 800°C. Results showed that H$_2$S concentration in the gas as low as 0.125 ppm can affect the cell voltage and the internal dry reforming process in SOFCs operating at 800°C within only 4 h of operation.

It was also observed that after poisoning the cell with 0.125 ppm of H$_2$S, the initial cell voltage slightly dropped (Figure 2). This can be attributed to incomplete sulphur desorption during cell recovery. The current-voltage (IV) curves were obtained with pure H$_2$ after recovering the cell and before the next reforming process. The IV curves (Figure 3) showed that H$_2$S caused a small drop in performance.

### 3.2 | Effect of H$_2$S on dry reforming on Ni-ScSZ at OCV

The experiment was repeated when the cell was at OCV. A decrease in the CH$_4$ reforming process was observed after two hours of injecting 0.125 ppm of H$_2$S in the fuel gas (Figure 4). The CH$_4$ reforming process and cell OCV decreased from 47% to 4% and 0.96 V to 0.85 V respectively in 3 h. When H$_2$S injection was stopped, methane reforming and OCV were recovered from 4% to more than 41%. This is also in agreement with Chattanathan et al. who observed that 0.5 mol% of H$_2$S caused a decrease in dry reforming to 19% using a Reformax 250 catalyst.
in a bed reactor. This research has revealed that even at purely catalytic conditions, H$_2$S as low as 0.125 ppm causes a severe decrease in dry reforming at operating conditions of SOFCs. While Johnson et al.$^{22}$ has reported that 25 ppm affects dry reforming on crashed anode catalyst (Ni-ScSZ and Ni-ScYSZ/Pd-CGO), we report that even 0.125 ppm can affect dry reforming on an electrochemically performing complete solid oxide fuel cell with Ni-ScSZ anode.

### 3.3 H$_2$S effect on dry reforming with and without a catalyst

Reforming has been assumed to take place on the cell and to a small extent on the current collector.$^{48}$ However, it is possible that other process equipment such as stainless steel may contribute to catalytic dry reforming.$^{49}$ Therefore, to test the catalytic reforming effect of H$_2$S purely on the cell, the experiment was carried out using the mica sheet (dummy cell) and the real cell without a current corrector.

To test the reforming and the effect of H$_2$S on reforming without catalysts (Ni-ScSZ cell and Pt current collector), the experiment was conducted using a dummy cell (mica sheet) in a ceramic block without platinum mesh (as the current collector) at 800°C. The same procedure was repeated using a real cell in a ceramic block without platinum mesh for comparison. It was observed that even when the cell was taken out (with mica sheet as a dummy cell), CH$_4$ dry reforming took place though lower than in presence of the cell. Figure 5 shows the effects of H$_2$S on dry reforming with and without the cell. With a dummy cell, the percentage of CH$_4$ reformed ($X_{CH4}$) was 8%. When 0.125 ppm H$_2$S was injected, $X_{CH4}$ decreased to 0.5% in 1 h. These could imply that H$_2$S could also affect the reforming reaction even without a cell. However, when H$_2$S was stopped, the CH$_4$ reforming was recovered. A similar trend was observed when a real cell (without platinum wire mesh) was used. A percentage of over 90% of CH$_4$ reforming was observed before injection of 0.125 ppm of H$_2$S in the fuel gas. When H$_2$S was injected, the $X_{CH4}$ decreased to below 20% and it was recovered when H$_2$S injection was stopped.

From Table 1, it appears from different authors that 1–2 ppm H$_2$S concentration is feasible for steam reforming using carbon-containing fuels. Also, Johnson et al.$^{22}$ observed that dry reforming was more tolerant to H$_2$S poisoning than steam reforming. However, from this research, dry reforming is greatly reduced by H$_2$S poisoning even at very low ppm levels, that is a 0.125 ppm H$_2$S concentration in the gas resulted in a significant decrease in the reforming process. This suggests that H$_2$S as low as 0.125 ppm affects the catalyst on the reforming sites of SOFCs.
4 | CONCLUSIONS

It has been observed that methane dry reforming in biogas-fuelled SOFC is affected by H₂S even at concentrations as low as 0.125 ppm H₂S in biogas with Ni-ScSZ cell. This H₂S concentration is far below the threshold of 1 ppm which is normally reported in literature. H₂S appeared to influence the reforming in the cell chamber even when the mica sheet (dummy cell) was used. Therefore, if biogas is to be used as fuel for SOFCs and internal dry reforming is envisaged, a stringent cleaning system is required, which can clean the gas to nearly zero ppm of H₂S level. With up to over 2000 ppm of H₂S concentration in biogas reported in literature, such a stringent gas cleaning system needs to be carefully designed to meet the conditions of internal dry reforming in SOFCs. Otherwise, an external reformer for dry reforming of CH₄ is required.

While we present the results obtained by our experiments, it appears that the influence of H₂S on different types of anodes under different fuel conditions including dry reforming needs detailed studies. Therefore, further studies are required to investigate the effect of H₂S in the presence of hydrocarbon fuels to facilitate SOFC systems design for real-life applications and material selection for systems components.
