ABSTRACT

Levees are small elevation ridges found on the edge between channels and shoals. They are known to develop along river channels during floods and along channels in alluvial deep water fans. Levees in tidal environments such as the Waddenzee are less pronounced (with a typical height in the order of 10 cm) and may be recognized by the fact that they become dry earlier than the surrounding mudflats, due to their higher elevation and coarser material. Levees form an essential link in the morphological interaction between tidal channels and shoals, although their development is yet poorly understood and requires further research.

We explore levee development by a process-based approach (Delft3D) both under highly schematized conditions and a realistic case study. The schematized approach concerns morphological development of a 2km long 100 m wide tidal channel with surrounding tidal flats. The levees develop during flood and further analysis shows the sensitivity to model parameters such as the diffusion coefficient, shoal width, grain size, and initial channel depth. The realistic case study concerns a tidal channel in a sub-embayment of San Francisco Estuary. 150 Years of bathymetric observations are coupled to a process-based morphodynamic modeling exercise explaining the levee development. Model results of the schematized setup and the San Pablo Bay case have in common that major accretion of the levees and the channel slopes occurs during flooding conditions.

INTRODUCTION

Levees are small elevation, coarse material ridges found on the edge between channels and shoals. They are known to develop along river channels during floods [Adams et al., 2004, Rowland et al., 2009, Brierley et al. 1997], along channels in alluvial deep water fans [Normark et al., 2002, Fildani et al., 2006, Straub and Mohrig, 2008], and along creek systems in salt marshes and mudflats during regular tidal forcing [Perillo and Iribarne, 2003, Temmerman et al., 2005, Wells et al., 1990].

Levees in tidal environments such as the Waddenzee are less pronounced (with a typical height in the order of 10 cm) and may be recognized by the fact that they become dry earlier than the surrounding mudflats, due to their higher elevation and coarser material. In a muddier environment Jaffe et al. [2007] report continuous measured narrowing of the tidal channel in San Pablo Bay over 150 years which may be interpreted as an expansion of the intertidal mudflats. Accretion takes place at the steep slope between channel and shoal, rather than at the edge of the shoal itself. It is not clear whether or not levee development and slope accretion are governed by similar processes and to what extent the sediment characteristics play a role in these types of channel shoal interaction.

AIM AND METHODOLOGY

Levee development forms an essential part in the morphodynamic interaction between channels and shoals although the governing processes are yet poorly understood and require further research. The aim of the current work is to investigate channel shoal interactions in more detail. Use is made of a process-based numerical model (Delft3D). Delft 3D solves the Reynolds averaged Navier Stokes equations, including the k-ε turbulence closure model, and applies a horizontal curvilinear grid with sigma layers for vertical grid resolution. It allows for salt-fresh water density variations, separate formulae for mud transport and sand transport, and variations in bed composition and specification (for example, bed layers with different percentages of mud and sand and spatial variation of critical shear stress). The impact of wind and waves can be added, so that, for example, the effects of wind set up and increased shear stress due to waves are taken into account. The applied wave model is SWAN of which a detailed description and its application in Delft 3D can be found respectively at the SWAN homepage (http://vlm089.citg.tudelft.nl/swan/index.htm), Booj et al. (1999) and Lesser et al. (2004). For every hydrodynamic time step (1 minute in this case) the flow module calculates water levels and velocities from the shallow water equations. Based on these hydrodynamic conditions and the wind field, the wave module calculates a wave field every hour and adds wave induced shear stresses to the shear stresses calculated from the flow module. The wave field is considered to be constant during one hour. Sediment transport is calculated from the resulting flow field and the bed is updated based on the divergence of the sediment transport field [Roelvink, 2006].

Our first step is to investigate channel shoal interaction under (very) schematized circumstances, i.e. by means of a 2 km long channel forced by tidal flow and additional sensitivity analysis on input parameters and processes. We will subsequently relate the outcome of the schematized model to a case study, i.e. San Pablo Bay, California, USA [Van der Wegen et al, 2010, 2011].
MODEL SETUP

Figure 1. Model grid for schematized conditions

Schematised model

Figure 1 shows the grid applied for the schematized model. The grid cell size is 10m in transverse direction and 5m in longitudinal direction. The channel has a width of the boundary limits. In the wider middle part of the model domain the channel is flanked by shoals. We suppose that the tide propagates from left to right. The boundary conditions on the west side and the eastside are described by a tidally varying water level with an amplitude of 1.75m and a period of 12 hours with a small water level phase difference between the boundaries to drive the tidal current defined by

\[ \Delta \varphi = \frac{360^\circ}{T} \sqrt{gh} L \]  

in which \( T \) (s) is the tidal period, \( g \) (m/s²) is the gravitational acceleration, \( L \) is the length of the model grid (m), \( h \) is the initial water depth in the channel (m). The standard settings apply Van Rijn transport formulations with constant D50.

San Pablo Bay model

Figure 2. Numerical grid of model covering San Pablo Bay and Suisan Bay. The upper branch at the landward side represents the Sacramento River and the lower branch the San Joaquin River.

Figure 2 shows the model domain applied in the San Pablo Bay case study. A curvilinear grid is applied on the domain and the condition for a stable and accurate computation (Courant number < 10) is met with a grid cell size of approximately 100 by 150 m and a time step of 2 minutes. Density currents and wave effects are included as well as 15 sigma layers describing the vertical grid distribution. The initial bathymetry is a measured (see Figure 3) and bed composition was derived as described by Van der Wegen et al. [2010].

The river discharge regime is modeled by a high river discharge 'wet' season and a low river discharge 'dry' season. This high level of schematization reduced river inflow to three practical 'tuning' parameters (i.e. duration of high discharge compared to low discharge and the magnitudes of the high and low river discharges). The landward river boundary conditions a derived from a larger 3D hydrodynamic model (Delft3D) covering a model domain ranging from the Delta to 20 km offshore including all sub-embayments of San Francisco Estuary [Van der Wegen et al. 2011]. In accordance with general observations salt concentration is set constant at zero at the landward boundary and at 31 psu at the seaward boundary. Prevailing wind conditions are schematized by a diurnal sinusoidal signal varying from 0 at midnight to 7 m/s at noon uniformly distributed over the domain. Every hour the SWAN model uses wind and hydrodynamic data from the flow calculation to generate a wave field and returns resulting adapted hydrodynamic parameters to the flow module. We apply 3 sand fractions modeled by Van Rijn transport formulation and five mud fractions modeled by the Krone-Pathenides formulation. Van der Wegen et al. [2011] provide further detail on the applied model formulations and schematizations.

MODEL RESULTS

Schematised model

Figures 4 and 5 present model results after 100 days of morphodynamic development. Clearly one can observe the levee development occurring at the shoals. The channel become more shallow and the levee develop up to more than 0.5 m in height. There is a significant variation along the channel, because the western levees have developed first. Small channels have evolved at ebb. The channels are located irregular intervals to drain the shoals at ebb, but aslo enhance flooding efficiency. Sensitivity analysis has been carried out on D50, sediment transport formulation, the bed slope factor, shoal dimensions (height, width and slope), height of mean water level and tidal amplitude, multiple sediment fractions including mud, application of wind and waves as well as channel curvature.
phases of the tidal cycle. However, main accretion of the slopes occurs during flooding conditions. The process-based modeling approach allows for a proper sensitivity analysis that enables to distinguish governing processes from secondary processes. For example, for the San Pablo Bay case study wind wave resuspension on the mudflats is necessary to let the westerly channel slopes accrete, whereas slope accretion on the easterly shoals is governed by dpoecistion during high river flow conditions.

San Pablo Bay model

Figure 6 shows the measured and modeled morphodynamic developments of the San Pablo Bay model over two different 30 year periods. One may clearly observe the resemblance between modeled and measured erosion and sedimentation patterns. Also, the development of the channel banks is pronounced and well reproduced by the model. This gives confidence to further analyse the underlying conditions and processes that govern channel slope and levee development by means of the (detailed) data generated by the model.

DISCUSSION AND CONCLUSION

Closer analysis of the model results shows that levee development in the schematized model and slope accretion in the San Pablo Bay model both occur mainly during flooding of the shoal area. The explanation is twofold. Rising water levels flood the shoals and transverse flow velocities (perpendicular to the channel) reduce considerably while entering the shoals so that sediment settles. Secondly, sediment concentrations increase because sediment transported in the large channel water column now enters a smaller water depth. The higher sediment concentration enhances settling of sediment as well. Especially the San Pablo Bay case includes more complexity since water flows are not nicely alligned with the channel direction and much more processes are included such as wind waves and multiple sediment fractions. Accretion and erosion occur both during different conditions.

ACKNOWLEDGEMENT

The research is part of the US Geological Survey CASCaDE climate change project (CASCaDE contribution *). The authors acknowledge the US Geological Survey Priority Ecosystem Studies, CALFED and Deltares for making this research financially possible.
