When a beam of light is laterally confined, its field distribution can exhibit points where the local magnetic and electric field vectors spin in a plane containing the propagation direction of the electromagnetic wave. The phenomenon indicates the presence of a nonzero transverse spin density. Here, we experimentally investigate this transverse spin density of both magnetic and electric fields, occurring in highly confined structured fields of light. Our scheme relies on the utilization of a high-refractive-index nanoparticle as a local field probe, exhibiting magnetic and electric dipole resonances in the visible spectral range. Because of the directional emission of dipole moments that spin around an axis parallel to a nearby dielectric interface, such a probe particle is capable of locally sensing the magnetic and electric transverse spin density of a tightly focused beam impinging under normal incidence with respect to said interface. We exploit the achieved experimental results to emphasize the difference between magnetic and electric transverse spin densities.

I. INTRODUCTION

The transverse spin density (TSD) of light describes field vectors, which spin transversely with respect to the local propagation direction of the electromagnetic wave [1–3]. In nature, such polarization states occur when electromagnetic waves experience strong lateral confinement since the appearance of transverse spin is intimately linked to the presence of longitudinal field components [1–3]. Typical optical systems exhibiting a TSD are waveguide modes [4–7], surface plasmon polaritons [8–10], near fields of nanostructures [11], whispering gallery modes [12], interfering plane waves [13], and tightly focused beams [14–16].

In recent years, a wide variety of applications have led to a continuously increasing interest in the TSD (see, for instance, Refs. [1–3,7] and references therein), particularly because of a related directional emission and coupling effect [17]. The phenomenon, which is often referred to as spin-momentum locking [18,19], can be used to implement spin-dependent signal routing [17,20,21] and single-atom optical devices such as isolators and circulators [22,23]. Thus, the TSD constitutes the foundation for novel quantum information processing concepts at the nanoscale [5,7]. Further potential applications of the TSD can be found in particle manipulation experiments in optical tweezers [10,13,14] and sensing, for example, of magnetically induced circular dichroism [24,25]. This interest in the TSD also led to the development of highly sensitive techniques, capable of measuring the TSD in propagating and evanescent waves [15,26].

Although the experimental techniques introduced in Refs. [15,26] are mainly concerned with the TSD of the electric field, from a theoretical point of view, both magnetic and electric components contribute equally to the total spin density $s$ [1–3]:

$$s = \text{Im}[\mu_0 \mathbf{H}^* \times \mathbf{H} + \epsilon_0 \mathbf{E}^* \times \mathbf{E}] / 4\omega \equiv s_H + s_E,$$

where $\omega$ refers to the angular frequency of the time-harmonic wave, $\mathbf{H}$ and $\mathbf{E}$ denote the magnetic and the electric fields, and $\mu_0$ and $\epsilon_0$ represent the permeability and the permittivity in vacuum. This equally weighted split into $s_E$ and $s_H$ is often referred to as dual symmetry [27] or electromagnetic democracy [28]. While in the highly symmetric case of a single circularly polarized plane wave the spin density is purely longitudinal and the magnetic and electric components are equal, $s_H^2 = s_E^2$ [1,2,28,29], in
more general fields of light, this equivalence of $s_H$ and $s_E$ does not hold.

Here, we explore, both theoretically and experimentally, the fundamental difference between the TSD of the magnetic and the electric field. At first, we theoretically elaborate on the distribution and composition of the TSD in the simplified exemplary scenario of a linearly polarized Gaussian beam. Then, we experimentally investigate the TSD of the magnetic and the electric field in tightly focused beams of light. While for the electric TSD a suitable measurement technique has been presented in Ref. [15], the magnetic component of the TSD has, to the best of our knowledge, not been experimentally studied so far. On these grounds, we detail, for the first time, a versatile experimental approach for reconstructing the TSD of the magnetic field at the nanoscale, which, at the same time, allows us to access the TSD of the electric field. Finally, we apply the technique to three different tightly focused polarization tailored beams of light and compare the reconstructed components of the respective TSD.

II. MAGNETIC AND ELECTRIC TRANSVERSE SPIN

We begin the discussion by exemplarily considering a paraxial, linearly $x$-polarized, monochromatic Gaussian beam of light, whose electric field distribution can be approximated by [30]

$$E(x, y, z) \approx E_0 \frac{z_0 e_x}{z_0 + iz} \exp \left[ ikz - \frac{kr^2}{2z_0 + 2iz} \right],$$

where $z_0$ and $E_0$ represent the Rayleigh range and amplitude of the beam, with $r = (x^2 + y^2)^{1/2}$ as a radial coordinate. Evidently, such a field distribution does not fulfill the transverse constraint of Maxwell’s equations—Gauss’s law in vacuum [31]—$\nabla \cdot E = 0$. However, it is possible to revise Eq. (2) accordingly by introducing a longitudinal field component [32,33]. In the focal plane ($z = 0$), a suitably adapted field distribution can be written as [1,2]

$$E(x, y) \approx E_0 \left( e_x + \frac{1}{z_0} i e_z \right) \exp \left[ -\frac{k r^2}{2z_0} \right].$$

Following this line of arguments, we can derive a similar expression for the focal distribution of the magnetic field of the described Gaussian beam. By starting with a $y$-polarized magnetic field—perpendicular to the $x$-polarized electric field—and by applying Gauss’s law of the magnetic field [31], $\nabla \cdot H = 0$, we obtain [1]

$$H(x, y) \approx H_0 \left( e_y + \frac{1}{z_0} i e_x \right) \exp \left[ -\frac{k r^2}{2z_0} \right].$$

with $H_0 = \sqrt{c_0/\mu_0 E_0}$. It is important to note that Eqs. (3) and (4) represent approximations and are only valid for paraxial or weakly focused Gaussian beams of light. However, the equations contain several important features, which illustrate the central message of this paper: a nonzero phase difference between longitudinal and transverse field components, and differing spatial distributions of the magnetic and the electric TSD.

At first, we elaborate on the relative phases of the individual field components. As indicated by the imaginary units in Eqs. (3) and (4), the longitudinal field components are $\pm \pi/2$ out of phase with respect to the transverse field components, resulting in transversely spinning magnetic and electric field vectors wherever the corresponding field components $H_y$ and $H_z$ or $E_x$ and $E_z$ overlap [2]. For further investigation of the resulting transverse spin, we calculate the focal spin density distribution by inserting Eqs. (3) and (4) in Eq. (1), which yields [1]

$$s \approx \left( c_0 E_0^x e_y - \mu_0 H_0^y e_x \right) \frac{\exp \left( -k \frac{r^2}{2} \right)}{2\omega z_0}.$$  

As we can see, $s$ is a purely transverse, azimuthally oriented vector field, since the longitudinal component $s^z$ is zero. For illustration, in Fig. 1(a), we depict the TSD, $s^x = s^x_H + s^x_E = (s^x_H + s^x_E) e_x + (s^x_H + s^x_E) e_y$ (see the yellow arrowheads), on top of the Gaussian distribution of the $x$ component of the electric field intensity ($|E_x|^2$), using $x$ and $y$ coordinates normalized to the beam waist $w_0 = (2z_0/k)^{1/2}$. The amplitude of the total TSD depends on the radial distance to the optical axis, but it is independent of the azimuth within the beam. However, despite the cylindrical symmetry of the total TSD, its type (electric or magnetic) changes depending on the azimuth. To emphasize the spatially dependent composition of the TSD, we plot the individual contributions $s^x_H$, $s^x_E$, $s^y_H$, and $s^y_E$ in Fig. 1(b). The TSD of the electric field exhibits a two-lobe pattern along the $x$ axis for $s^y_E$, while the lobes of the TSD of the magnetic field are arranged along the $y$ axis for $s^y_H$. Different color codes are used to highlight the differences between magnetic and electric TSDs. The two distributions of $s^y_H$ and $s^y_E$ are rotated by $90^\circ$ with respect to each other, which is a direct consequence of the orthogonality of the magnetic and electric transverse field components of the linearly polarized Gaussian beam exemplarily studied here.

In conclusion, the results we derived from this simplified model beam highlight the difference of the distributions of $s^y_H$ and $s^y_E$ in spatially confined light [1]. This notion is essential, for instance, in spin-momentum locking experiments based on silicon nanophotonics [21,34], where both electric and magnetic dipolar modes are supported [35–37]. The example also emphasizes the importance of distinguishing $s^y_H$ and $s^y_E$ experimentally [21]. While techniques
for measuring $s_E^\perp$ have been presented recently [15,26], in the following we discuss a measurement concept for $s_H^\perp$, allowing for a direct comparison between $s_H^\perp$ and $s_E^\perp$ in complex and highly confined light fields.

### III. EXPERIMENTAL CONCEPT

Our experimental approach for simultaneously measuring $s_H^\perp$ and $s_E^\perp$ relies on a field probe that exhibits a magnetic as well as an electric dipole resonance. In this regard, suitable field probes, which support both types of modes, are high-refractive-index nanoparticles [35,38,39]. Here, we utilize a silicon (Si) nanosphere with core radius $r_{Si} = 79$ nm and an estimated silicon dioxide (SiO\textsubscript{2}) shell of thickness $\delta = 8$ nm as a probe. The particle is sitting on a glass substrate [see sketch in Fig. 2(a)] attached to a 3D-piezo stage, enabling us to scan the field probe through the focal plane of a tightly focused beam. A scanning electron micrograph of the particle is shown in the inset. In order to understand the actual scattering behavior of our probe, we first analyze its scattering cross section [see Fig. 2(b)] using Mie theory [40]. For the calculation, we assumed a particle in free space, not considering the glass substrate. The black line indicates the total scattering cross section of the particle, with the red and blue lines representing the contributions of the magnetic and electric dipolar modes, respectively. Due to the spectral overlap between the electric and magnetic resonances, a generic input field excites a dipolar mode with simultaneously electric and magnetic contributions in the shown spectral range [35,38,41,42]. With the objective to induce electric and magnetic dipole moments with a comparatively high efficiency, we choose an excitation wavelength between the maxima of both resonances (here, $\lambda = 630$ nm) for the TSD sensing experiment. Using a point dipole approximation, the electric ($p$) and magnetic ($m$) dipole moments of the particle are thus both proportional to the local excitation fields, $p \propto E$ and $m \propto H$, while higher-order multipoles can be neglected.

The direct link between the excitation field and the induced dipole moments is the basis of our TSD reconstruction approach. When we can determine the magnetic and the electric transversely spinning dipole moments of our probe particle from the light that it scatters into the far field, we effectively measure the TSD of the...
excitation field [15]. In order to achieve an unambiguous
reconstruction of $s^k_H$ and $s^k_E$, a detailed analysis of the
simultaneous emission of magnetic and electric dipoles
close to a dielectric interface is required.

In comparison to a dipole in free space, the far-field
emission pattern of a dipole above a dielectric substrate is
strongly altered by the air-glass interface [32,43]. Because
of the dominant emission of a dipole into the higher-index
material [43], we are specifically interested in the light
transmitted into the glass half-space. To calculate the
directional emission, we use a plane-wave decomposition
with the transverse electric ($E_x$) and transverse magnetic
($E_p$) polarization states as a basis. Following Ref. [32],
the far field in the glass half-space, $E_f = E_p e_p + E_x e_x$, of an
arbitrarily polarized electromagnetic dipole can be written
in compact form as

$$E_f(k_x, k_y) \propto C \hat{T}(\mathbf{M} \mathbf{p} + \hat{\mathbf{R}} \hat{\mathbf{M}} \mathbf{m}/c_0),$$

(6)

with $C = (k_0^2 n^2 - k_z^2)^{1/2}/k_z \exp[i(k_z d)$. The transverse
wave number is defined as $k_z = (k_0^2 - k_z^2)^{1/2}$, while the
longitudinal wave number can be calculated by
$k_z = (k_0^2 - k_z^2)^{1/2}$. The parameter $d$ represents the distance
between the dipole and the interface, and $c_0$ refers to the
vacuum speed of light. The matrix $\hat{T}$ consists of the Fresnel
transmission coefficients $t_s$ and $t_p$ [32],

$$\hat{T} = \begin{pmatrix} t_p & 0 \\ 0 & t_s \end{pmatrix},$$

(7)

while $\hat{\mathbf{M}}$ is a rotation matrix, representing the overlap of the
electric and the magnetic dipole moments with the field
vectors of the plane waves of the angular spectrum [44],

$$\hat{\mathbf{M}} = \begin{pmatrix} \frac{k_x}{k_z k_0} & k_y k_0 & -\frac{k_y}{k_z} \\ -\frac{k_x}{k_z} & k_x k_0 & 0 \\ \frac{k_y}{k_z} & -k_y k_0 & \frac{k_x}{k_z} \end{pmatrix}.$$

(8)

To calculate the far field of the magnetic components of the
dipole emitter, a second rotation matrix $\hat{\mathbf{R}}$ is introduced,
which is required because of interchanging electric and
magnetic field vectors [31,32]:

$$\hat{\mathbf{R}} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

(9)

We utilize Eq. (6) to exemplarily calculate the far-field
emission pattern ($I = I_p + I_s \propto |E_p|^2 + |E_s|^2$) of a mag-
netic dipole spinning around an axis parallel to the air-glass
interface. For $\mathbf{m} = (0, 1, i)$, we obtain the emission pattern
depicted as the side-view plot in Fig. 2(c), where, for the
sake of completeness, we show the emission into the air
half-space as well. For the distance between the dipole and
the interface in the calculations, we use the radius of the
particle, $r_0 = r_S + \delta = 87$ nm. We see that, similar to a
transversely spinning electric dipole moment (see, for
example, Refs. [20,45]), the transversely spinning magnetic
dipole moment results in a directional far-field emission
into the angular region above the critical angle [$k_z > k_0$,
$k_z = (k_0^2 - k_z^2)^{1/2} = i|k_z|$]. By assuming $\mathbf{m} \propto \mathbf{H}$, this links
the TSD of the magnetic field to the far-field directionality.

In this context, the objective of the following theoretical
discussion is the derivation of a quantitative connection
between the TSD (magnetic and electric) and the direc-
tional emission pattern of the probe particle above the
critical angle. For that purpose, we need to calculate the
difference of the light scattered into opposite transverse
directions for a general electromagnetic dipole [15]. First,
we consider the directionality along the $x$ direction, $k_x = \pm k_z$ and $k_y = 0$, and above the critical angle, $k_z > k_0$.
Calculating the difference between the light scattered in the
positive and negative $x$ directions for both polarization
states, $\Delta_x^k I_p = I_p(k_z, 0) - I_p(-k_z, 0)$ and $\Delta_x^k I_s = I_s(k_z, 0) - I_s(-k_z, 0)$, results in

$$\Delta_x^k I_p \propto D |t_p|^2 \left[ \frac{|k_x| \text{Im}(p_x^m p_z)}{k_0 c_0} - \frac{\text{Re}(m_x^p p_z)}{c_0} \right],$$

(10)

$$\Delta_x^k I_s \propto D |t_s|^2 \left[ \frac{|k_x| \text{Im}(m_x^p m_z)}{k_0 c_0} + \frac{\text{Re}(p_x^m m_z)}{c_0} \right].$$

(11)

with $D = 4|C|^2 k_z/k_0$. By performing a similar calculation for the $y$ direction, $\Delta_y^k I_p = I_p(0, -k_z) - I_p(0, k_z)$ and $\Delta_y^k I_s = I_s(0, -k_z) - I_s(0, k_z)$, we obtain

$$\Delta_y^k I_p \propto D |t_p|^2 \left[ \frac{|k_y| \text{Im}(p_y^m p_z)}{k_0 c_0} - \frac{\text{Re}(m_y^p p_z)}{c_0} \right],$$

(12)

$$\Delta_y^k I_s \propto D |t_s|^2 \left[ \frac{|k_y| \text{Im}(m_y^p m_z)}{k_0 c_0} + \frac{\text{Re}(p_y^m m_z)}{c_0} \right].$$

(13)

For each of Eqs. (10)–(13), we can discern two different
terms. The first terms include only electric or magnetic
dipole components, while the second terms consist of a
mixture of both electric and magnetic dipole components.
A comparison of the purely magnetic and purely electric
terms with the magnetic and electric components of the
TSD—$s_1^H \propto \text{Im}(H_x^2 H_z)$, $s_2^H \propto \text{Im}(H_x H_z^2)$, $s_1^E \propto \text{Im}(E_x E_z^2)$, and $s_2^E \propto \text{Im}(E_x^2 E_z)$—reveals a strong similarity. Considering
the aforementioned dipole approximation of the
scattering response of the particle, $\mathbf{p} \propto \mathbf{E}$ and $\mathbf{m} \propto \mathbf{H}$, we see that the first terms in Eqs. (10)–(13) are proportional to
the individual components of the TSD. However, the four
equations contain additional terms, which represent the
interference of electric and magnetic dipole components.
A simple difference measurement of the scattered light—as
discussed in Ref. [15]—would therefore not be sufficient to
reconstruct the TSD. Nonetheless, it is possible to unambiguously distinguish between the terms representing the TSD and the nonrelevant electromagnetic interference terms by measuring the directional emission for two different transverse wave numbers, \( k_{1,1} \) and \( k_{1,2} \), since only the terms corresponding to the TSD exhibit factors depending on \( k_x \). For example, by measuring \( \Delta^{k_{1,1}} I_s \) and \( \Delta^{k_{1,2}} I_s \), we obtain two linearly independent equations, which can be solved for the term representing \( s_H^y \). The same approach can be utilized for the three other components of the transverse spin density—\( s_H^x \), \( s_E^y \), and \( s_E^x \).

With this theoretical consideration in mind, we can finally design an experimental procedure, capable of measuring the magnetic and electric TSDs of an incoming tightly focused beam. Figure 2(d) shows a sketch of our setup. A polarization tailored beam is tightly focused by a microscope objective with NA = 0.9. The resulting focal field is probed by the Si particle immobilized on a glass substrate. The probe can be scanned through the focal plane by a 3D-piezo stage. Below the substrate, an oil immersion-type objective with NA = 1.3 collects the light transmitted through the interface and scattered into the glass half-space. The far-field emission pattern of the particle, to be observed in the back focal plane (BFP) of the collection objective, is subsequently analyzed in its polarization distribution. Hence, the collected light is passed through a WP, splitting the beam into two orthogonal polarization states. Imaging the BFP with a lens through the WP onto a camera therefore results in two BFP images representing a decomposition into \( x \) and \( y \) polarization, respectively.

To exemplarily demonstrate the reconstruction of \( s_H^x \) and \( s_H^y \) from such polarization-resolved BFP images, we place the Si probe in the focal plane of a tightly focused linearly \( x \)-polarized Gaussian beam, and we shift the particle with respect to the center of the focal spot by 150 nm along the \( y \) direction. The resulting \( x \)- and \( y \)-polarized BFP intensity distributions, \( I_x \) and \( I_y \), are shown in Figs. 3(a) and (b). In order to determine \( s_H^x \) and \( s_H^y \) for this position of the probe particle, we average the far-field intensity in \( 2 \times 4 \) small regions in both BFP images (see small black circles) and obtain \( I_{x,i} \) and \( I_{y,j} \), with \( i = 1, 2, 3, 4 \) indicating the azimuthal position and \( j = 1, 2 \) referring to two different transverse \( k \) vectors, \( k_{1,1}/k_0 \equiv 1.1 \) and \( k_{1,2}/k_0 \equiv 1.25 \). It is important to note that, although we measured the BFP images in the \( x \)- and \( y \)-polarization basis, we can assign the indices \( p \) and \( s \) to the averaged intensity values since, along the \( k_x \) and \( k_y \) axes in \( k \) space, the transverse magnetic and transverse electric polarization basis coincides with the \( x \)- and \( y \)-polarization basis. Therefore, the distribution of \( s_H^x \propto \text{Im}(m_5m_3) \) can, for example, be calculated from \( \Delta^{k_{1,1}} I_s = I_{s,3} - I_{s,1} \) and \( \Delta^{k_{1,2}} I_s = I_{s,3} - I_{s,1} \).

**IV. EXPERIMENTAL RESULTS AND DISCUSSION**

At first, we utilize our approach to reconstruct the TSD components of a tightly focused linearly \( x \)-polarized Gaussian beam. Considering the simplified TSD distribution described in Eq. (5) and depicted in Figs. 1(a) and 1(b), we expect to obtain two-lobe patterns for \( s_H^y \) and \( s_E^x \) rotated by 90° with respect to each other. The actual experimental results are shown in the left column of Fig. 4, while a sketch of the cross section of the input beam is shown in the inset above (red and gray vectors indicate \( x \)-polarized electric and \( y \)-polarized magnetic fields, respectively). We clearly recognize the expected two-lobe patterns of \( s_H^y \) and \( s_E^x \), shown in Figs. 4(a) and 4(d), and we observe their rotation of 90° with respect to each other. The experimental results are in very good agreement with the theoretical distributions (see insets) calculated with vectorial diffraction theory [32,46]. Minor deviations are caused by imperfections of the incoming beam, the probe particle, and the elements in the detection path. In particular, imaging the BFP after passing through the WP can be identified as one of the main sources of error since the two partial beams are impinging.
ont to the imaging lens under an angle [see Fig. 2(d)] and the optical path lengths through the WP are slightly different for x- and y-polarized light. It should also be mentioned here that, in contrast to the simplified TSD distributions in Fig. 1(b), where \( s_H^x \) and \( s_E^x \) are exactly zero, both distributions exhibit weak four-lobe patterns in the case of a tightly focused beam [see insets in Figs. 4(b) and 4(c)]. Although the measured distributions of \( s_H^x \) and \( s_E^x \) are indeed much weaker than the two-lobe patterns of \( s_H^y \) and \( s_E^y \), they do not perfectly resemble the theoretical expectations. Nonetheless, it can be seen that our measurement approach is sensitive and allows for demonstrating the main features of \( s_H^y \) and \( s_E^y \) for the case of a tightly focused linearly polarized Gaussian beam.

In order to verify our experimental scheme and additionally explore and highlight differences between the magnetic and the electric TSD in more complex light fields, we investigate two tightly focused cylindrical vector beams with azimuthal and radial polarization distributions. We have chosen these beams because they can be transformed from one to the other by interchanging electric and magnetic fields, allowing for cross-checking of our experimental results. As an illustration, we depict sketches of the incoming azimuthally and radially polarized beams as insets on top of the central and right columns of Fig. 4, respectively. As we can see, the azimuthal polarization of the electric field is accompanied by a radially polarized magnetic field, while the radial polarization of the electric field implies an azimuthally polarized magnetic field.

An important feature of azimuthally polarized beams is their purely transverse electric field distribution, which remains purely transverse even when the beam is tightly focused [47]. Therefore, the electric TSD must be zero. In contrast, the magnetic field of such a tightly focused beam exhibits a strong longitudinal component [41] and, in particular, transversely spinning magnetic fields. The theoretical predictions and the experimentally measured distributions of \( s_H^y \) and \( s_E^y \) are shown in Figs. 4(e)-4(h). We see a good overlap of theory and experiment, effectively verifying the aforementioned statements. In particular, we see a strong magnetic TSD and a very weak (theoretically zero-valued) electric TSD.

When comparing these results with the distributions of the tightly focused radially polarized beam plotted in Figs. 4(i)-4(l), we see that, as expected, \( s_H^x \) and \( s_E^x \) are essentially interchanged. This time, we obtain a strong electric TSD accompanied by a weak (ideally zero-valued) magnetic TSD. The apparent minor rotations of the experimental distributions of \( s_E^y \) with respect to the theoretical prediction are caused by aberrations of the incoming beam and deviations in the response of the probe particle in combination with the aforementioned imperfections of the detection path.

V. CONCLUSION

In conclusion, we presented a probe-based scanning technique, which allows for the simultaneous reconstruction and distinction of the TSD of the magnetic and the electric field. This was achieved by analyzing the far-field directionality of the light scattered off the nanoprobe. We utilized the technique to emphasize the importance of
distinguishing the magnetic and the electric components of the TSD in the case of highly confined light. In the process, we demonstrated the difference between the distributions of $s_H^2$ and $s_E^2$ in a tightly focused linearly polarized beam. In particular, we showed their $90^\circ$ rotation with respect to each other. Additionally, we investigated $s_H^2$ and $s_E^2$ in tightly focused azimuthally and radially polarized beams. Thereby, we emphasized that the radially polarized beam exhibits purely electric TSD, while the azimuthally polarized beam exhibits purely magnetic TSD.

These beams can be used, for instance, to distinguish whether an observed effect is dependent on $s_H^2$, $s_E^2$, or their interplay. A possible application can be found in the optical manipulation of particles exhibiting magnetic and electric dipole resonances. There, azimuthally and radially polarized beams could be used to investigate light-matter spin-angular-momentum transfer for magnetic and electric fields individually [13,48]. On the other hand, the interplay between $s_H^2$ and $s_E^2$ can be an important factor in magnetoelectric coupling [48,49].

From a general and more conceptional point of view, although the interaction of light and matter is, in many scenarios, mainly governed by the electric field and the corresponding spin density, our results demonstrate the relevance of the dual symmetry (electromagnetic democracy) representation of the spin angular momentum of light. In this regard, our work takes its place alongside recent experimental efforts to distinguish the different and more elusive components of linear and angular momenta of light [50].

Most importantly, by being able to influence and tailor the magnetic and electric parts of the TSD separately, we anticipate that the spin-momentum locking of transversely spinning magnetic dipoles, an effect that has recently been investigated in Refs. [51,52], will gain relevance in upcoming experimental and theoretical studies, similar to the spin-momentum locking of spinning electric dipoles [1–3,7]. Especially in the field of silicon-based nanophotonics [35–37], the spin-momentum coupling of combined electric and magnetic dipoles represents a promising route towards signal routing and polarization multiplexing at the nanoscale.
