The realization of nonclassical states of light has opened up the possibility of using quantum optics for a variety of applications in quantum sensing [1–3], and quantum information science [4,5], as well as for extremely sensitive measurements [6]. Optomechanical systems, on the other hand, offer an exciting opportunity to study the quantum states of macroscopic systems [7]. Considerable progress has been made in controlling these massive systems down to the quantum level. Recent breakthroughs include optomechanical squeezing of light [8,9] and of mechanical motion [10,11], quantum entanglement between mechanics and a cavity field [12,13], as well as between two mechanical oscillators [14,15], and nonclassical photon-phonon correlations by measuring the second-order cross-correlation $g^{(2)}$ [16].

Recent interest has focused on generating non-Gaussian states of mechanical systems, e.g., preparing the mechanical oscillator in a single-photon Fock state. Following several theory proposals [13,17], this has been realized by exploiting the optomechanical parametric down-conversion combined with single-photon detection [18], in close analogy to early quantum optics experiments. It could also be generated by transferring the single-photon state from an optical field to a mechanical resonator (MR) [19]. Alternative ways to create non-Gaussian states of a mechanical system include exploiting the intrinsic nonlinearity of the optomechanical interaction [20], or by making measurements on the optical field [21]. The preparation of such nonclassical states of a massive object is important in connection with the studies of quantum effects at the macroscopic scale [22,23]. There are many other non-Gaussian states, such as quantum superposition states [24], and excitation-added or -subtracted coherent and squeezed states [25–27]. The addition of excitations on a coherent state, for example, provides a way to observe quantum effects of a radiation field, such as quadrature squeezing, sub-Poissonian character, and negative Wigner distributions [26]. Single-photon-added coherent states of light have been generated using parametric down-conversion in a nonlinear crystal in combination with single-photon detection [28]. In this Rapid Communication, we apply this concept to the motional state of a mechanical oscillator. Specifically, we work on cavity optomechanics [7] and provide a full scheme to generate and detect single-phonon-added coherent states (PACS) of mechanical motion [25]. As a first step, we prepare the MR in a coherent state using electromagnetically induced transparency [29], or equivalently, optomechanically induced transparency (OMIT) [30], where the cavity is bichromatically driven by a strong red-detuned field and a much weaker field on cavity resonance. The former can also help cool the mechanical motion close to its quantum ground state [31,32], and the latter is used to displace the ground state in phase space to a coherent state. We then add a single phonon onto the coherent state via optomechanical parametric down-conversion combined with single-photon detection. This can be realized by sending a weak blue-detuned laser pulse into the optomechanical cavity. Finally, we confirm the generated phonon state by using a relatively strong red-detuned pulse which realizes a state-swap operation between the MR and the light pulse. We then measure the Mandel $Q$ parameter of the cavity output field, confirming the sub-Poissonian character of the mechanical state. Alternatively, homodyning the cavity output and measuring the variance of the quadrature can be used to detect squeezing of the mechanical state. Lastly, we analyze the effects of residual thermal excitations in the coherent-state-preparation stage on the results of the ideal case where the mechanical motion is cooled exactly into its quantum ground state (mean phonon number $\bar{n}_0 = 0$).
Preparing mechanical coherent states. We consider an optical cavity mode with resonance frequency $\omega_c$ and annihilation (creation) operator $a \ (a^\dagger)$ $(\{a,a^\dagger\} = 1)$ coupled to a MR with frequencies $\omega_m$ via radiation pressure, as depicted in Fig. 1(a). The cavity mode is bichromatically driven by a strong red-detuned field at $\omega_m \sim \omega_m - \omega_m$ and a much weaker field on cavity resonance $\omega_m \sim \omega_m$. The Hamiltonian of the system reads

$$H = \hbar \omega_c a^\dagger a + \frac{1}{2} \hbar \omega_m (q^2 + p^2) - \hbar g a^\dagger a q + i \hbar [E_0 e^{-i\omega_m t} + E_1 e^{-i\omega_m t} a^\dagger - \text{H.c.}]. \quad (1)$$

Here, $q$ and $p$ are the dimensionless position and momentum quadratures of the MR satisfying the commutation relation $[q, p] = i \hbar$. $g$ is the single-photon optomechanical coupling rate. $E_0$ and $E_1$ are respectively related to the power of the driving fields $P_0$ and $P_1$ ($P_1 \ll P_0$) by $|E_0|^2 = 2 \kappa P_0/\hbar \omega_0$ and $|E_1|^2 = 2 \kappa P_1/\hbar \omega_0$, where $\kappa$ is the cavity decay rate. Such a system has been employed for the study of OMIT in cavity optomechanics [29,30]. Instead of looking at the mean-field response of the system to the probe field, we focus on the mechanical part here and include quantum fluctuations. The mechanical motion can be cooled close to its quantum ground state ($\hbar_0 \ll 1$) when the system is working in the resolved sideband limit and has a large cooperativity [31,32]. We work in this deep cooling regime and show that by including a weak “probe” field, the MR can be prepared in a coherent state, where the averages of the mechanical quadratures show periodic behaviors [33], while the fluctuations almost remain unchanged. This can easily be understood: The red-detuned strong light beam realizes an effective beam-splitter interaction which maps the coherent state of the weak field on cavity resonance onto the mechanical state [34].

By taking average values and using the factorization $(AB) \simeq (A) (B)$ ($A$ and $B$ are arbitrary system operators), we obtain the Langevin equations (QLEs) describing the quantum fluctuations ($\delta q, \delta p, \delta x, \delta y$), with $\delta x = (\delta a + \delta a^\dagger)/\sqrt{2}$ and $\delta y = i(\delta a^\dagger - \delta a)/\sqrt{2}$, are given by

$$\dot{\delta q} = -\omega_m \delta p,$$

$$\dot{\delta p} = -\omega_m \delta q + \gamma \delta p + \sqrt{2} \sum_{n=0,1} e^{-i\omega_m t} (G_n^x \delta x + G_n^y \delta y) + \xi,$$

$$\dot{\delta x} = -\kappa \delta x + \Delta \delta y - \sqrt{2} \sum_{n=0,1} e^{-i\omega_m t} G_n^y \delta q + \sqrt{2} \kappa x^m,$$

$$\dot{\delta y} = -\kappa \delta y - \Delta \delta x + \sqrt{2} \sum_{n=0,1} e^{-i\omega_m t} G_n^x \delta q + \sqrt{2} \kappa y^m,$$

where we have defined $G_n^x = \text{Re} G_n$ and $G_n^y = \text{Im} G_n \ (n = 0, 1)$, and assumed time-dependent detuning $\Delta = \Delta_0 - g(q) \sim \Delta$, which is a good approximation when $|E_1| \ll |E_0|$. $\xi$ and $\kappa x^m y^m$ are input noise operators for the mechanical and cavity mode, respectively, which are zero mean and characterized by the correlation functions $\langle \xi(t) \xi(t') \rangle \sim \gamma (2n+1) \delta (t-t')$ [in the Markovian approximation valid in current experimental regime, and $\overline{n} = \langle \frac{\hbar \omega_0}{4} + 1 \rangle$ is the mean thermal phonon number], and $\langle x^m(t) x^m(t') \rangle = \langle y^m(t) y^m(t') \rangle = \frac{1}{2} \delta (t-t')$. The correlators are different.
because the way quantum noise affects the field in the cavity and the MR. The vacuum noise enters the cavity and thus it gets directly added to the field mode. For the MR the Brownian noise acts on a massive system, i.e., it acts as a force and thus affects the momentum of the MR. The QLEs (4) can be conveniently solved in the frequency domain [35], and analytical expressions of $\langle \delta q^2 \rangle$ and $\langle \delta p^2 \rangle$ can be achieved, which are, however, too lengthy to be reported here. Nevertheless, we find numerically that the “probe” field has a negligible effect on the fluctuations of $\langle \delta q^2 \rangle$ and $\langle \delta p^2 \rangle$ provided that $|E_1| \ll |E_0|$ [35]. Adopting the parameters from a recent experiment [18], $\omega_m/2\pi = 5.25$ GHz, $\gamma = \omega_m/3.8 \times 10^5, \kappa/2\pi = 846$ MHz, $g/2\pi = \sqrt{2} \times 869$ kHz, and considering relatively higher temperatures $T = 1$ K (10 K), corresponding to $\hbar \approx 3.49$ (39.19), we obtain $\langle \delta q^2 \rangle \approx 0.5139 (0.5887)$ and $\langle \delta q^2 \rangle$, and $\langle \delta p^2 \rangle \approx 0.5138 (0.5886)$ for pump powers $P_0 = 50$ µW and $P_1 = 5$ µW (which gives $|E_1/|E_0| = 0.1 \ll 1$, where $\delta q^2$ and $\delta p^2$ are fluctuation modulation terms due to the weak “probe” field. These modulation terms are negligible with respect to $\langle \delta q^2 \rangle \approx 0.5139 (0.5887)$ and $\langle \delta p^2 \rangle \approx 0.5138 (0.5886)$ [corresponding to $\hbar = 0.0138 (0.0886)$] when the “probe” field is absent [35], and thus the MR is prepared approximately in a coherent state. This directly follows from the linearity of Eq. (4).

Adding a phonon onto coherent states. Once the MR is prepared in the desired coherent state, we switch off the pump and “probe” fields. After a time $\kappa^{-1} \ll \tau_{pd} \ll \gamma^{-1}$ [see Fig. 1(b)], all cavity phonons decay and the mechanical state remains effectively unchanged. The system is then in the state $|0\rangle_c |\beta_m\rangle$, where $|\beta| = \sqrt{2} |<q|_0| \leq \sqrt{2} \omega_m/\kappa$, when $\kappa \ll \omega_m$ and $C_0 \gg 1$. Using the parameters of Ref. [18] and taking $P_0 = 0.2$ mW, 5.4 pW $< P_1 < 48$ pW corresponds to a coherent state with amplitude $1 < |\beta| < 3$, where, as we will show later, the mechanical squeezing is most notable. Note that, in practice, the MR is prepared in a thermal coherent state (e.g., due to the absorption heating) with thermal phonon occupancy $\hbar \approx 1$. We shall first consider the case of $\hbar = 0$ and then study the effect of the residual excitations on the results of this idealized case.

Adding a single phonon onto a coherent state can be implemented by sending a weak blue-detuned write pulse at $\omega_\delta \approx \omega_c - \omega_m$, which yields the effective Hamiltonian $H_b = \hbar G_b (a b^\dagger + a b)$ [35], where $b = (q + i p)/\sqrt{2}$, $G_b = g/\omega_m/\sqrt{2}$ is the effective optomechanical coupling rate, and $n_b = 2 \kappa^2 P_b/|\hbar \omega_0(\kappa^2 + \omega_m^2)|$ is the intracavity photon number ($P_b$ is the power of the pulse). To simplify the model, we consider flattop pulses. This Hamiltonian generates a two-mode squeezing interaction (with a small squeezing parameter since $G_b \tau_b$ is assumed to be small; $\tau_b$ is the pulse duration).

The state of the system after the pulse can be approximated as

$$|\phi \rangle \approx (1 + \mathcal{P} a^\dagger b^\dagger) |0\rangle_c |\beta_m\rangle + \mathcal{P}|1\rangle_c |b^\dagger |\beta_m\rangle,$$

where $|\mathcal{P}| = G_b \tau_b \ll 1$. The MR is conditionally prepared in a single-PACS $b^\dagger |\beta_m\rangle$ if a single photon is detected. In what follows, we derive the exact solution of the system state after applying the write pulse. We consider the pulse duration to be much shorter than the mechanical decoherence time $\tau_b \ll \gamma^{-1}$, such that the decay of mechanical energy can be neglected. This leads to the QLEs during the write pulse, $\dot{\delta a} = -\kappa \delta a + i G_b \delta b^\dagger + \sqrt{2} \kappa a^\dagger \delta b$, and $\delta b = i G_b \delta a$ [35]. We consider also a weak coupling $G_b \ll \kappa$, allowing for adiabatic elimination of the cavity mode, and we thus have $\delta a \approx \kappa^{-1} (i G_b \delta b + \sqrt{2} \kappa a^\dagger \delta b)$. Using the standard input-output formula [36] $A_{out} = \sqrt{2} \kappa a - \delta a^\dagger$, we obtain $A_{out} \approx i \sqrt{2} G_b \delta b^\dagger + \delta b^\dagger$, and $b = g_b \delta b^\dagger + i \sqrt{2} G_b \delta b^\dagger$, where $G_b = G_b^2/\kappa$. We introduce the temporal modes for the cavity driven by the write pulse of duration $\tau_b$, $A_{out}^{\text{m.tbl}}(\tau_b) = \{ \pm \sqrt{2} G_b/(1 - e^{-2\kappa \tau_b}) \}^{1/2} \int_0^{\tau_b} e^{i \delta q(t) \tau_{pd} / 2} \text{d} \tau_{pd}$ [36]. This leads to the expressions $A_{out}^{\text{m.tbl}}(\tau_b) = \sqrt{2} G_b \delta b^\dagger + i \sqrt{2} G_b \delta b^\dagger - i \tau_{pd}(0)$, and $b^{\tau_b}(t) = e^{i \sqrt{2} G_b t}(0) + i e^{i \sqrt{2} G_b t} - i \tau_{pd}(0)$. A propagator $U(t_\beta)$ that satisfies $A_{out}^{\text{m.tbl}}(t_\beta) = U^\dagger A_{out} \delta b^\dagger \delta b\rangle$ is then prepared with a high probability $A_{out}^{\text{m.tbl}}(t_\beta) = U^\dagger A_{out} \delta b^\dagger \delta b\rangle$ [17], where $Z(t_\beta) = e^{-\sqrt{2} G_b t_\beta} - 1 \leq 1$. For an initial state $|0\rangle_c |\beta_m\rangle$, the system, at the end of the pulse, is prepared in the state

$$|\phi(t_\beta)\rangle = Z e^{-\frac{i |\beta|^2}{2} (1 - Z^2)} \int_0^\infty \frac{\text{d} |n|}{n!} (A_{out}^\dagger)^n \langle 0 | c | Z \beta \rangle_m \approx Z e^{-\frac{i |\beta|^2}{2} (1 - Z^2)} |0\rangle_c |Z \beta \rangle_m + i \sqrt{1 - Z^2} |1\rangle_c |Z \beta \rangle_m.$$

(6)

For taking “$\approx$” in Eq. (6), we have assumed $1 - Z(t_\beta) \ll 1$ ($G_b \tau_b \ll 1$, i.e., the probability of generating one photon-phonon pair is sufficiently low, such that the possibility of generating more than one photon-phonon pair is negligible. The MR is then prepared with a high probability in a single-PACS $b^\dagger |Z \beta \rangle_m$, with a slightly reduced amplitude $|\beta| \rightarrow |\beta| e^{-\sqrt{2} G_b t_\beta}$, provided that a single photon is detected on cavity resonance. This probability can be as high as 98.8% in the experiment [18]. This is similar to the proposals [17,37] and experiments [18,28] for preparing single-photon and single-phonon states.

Readout of PACS. The photon state can be read out by sending a red-detuned laser pulse at $\omega_\delta \approx \omega_c - \omega_m$, which yields the effective Hamiltonian $H_r = \hbar G_r (a b^\dagger + a b)$ [35], with the effective coupling rate $G_r = g/\sqrt{n_r/2}$, and the intracavity photon number $n_r = 2 \kappa^2 P_r/|\hbar \omega_0(\kappa^2 + \omega_m^2)|$ ($P_r$ being the power of the pulse). Again, we assume $|\beta| \ll \gamma^{-1}$ and neglect the mechanical damping. The QLEs during the readout pulse are $\dot{\delta a} = -\kappa \delta a + i G_r \delta b^\dagger + \sqrt{2} \kappa a^\dagger \delta b$, and $\delta b = i G_r \delta a$ [35]. Following the same procedures as in the last section, we obtain the temporal mode of the cavity output field, $A_{out}^{\text{m.tbl}}(t_\beta) = B(t_\beta) A_{out}^{\text{m.tbl}}(t_\beta) + i \sqrt{1 - B(t_\beta)} \langle \beta \rangle_m$, where $B(t_\beta) = e^{-\sqrt{2} G_r t_\beta}$, $0 < B(t_\beta) \leq 1$, and $G_r = G_r^2/\kappa$. It is clear that $A_{out}^{\text{m.tbl}}(t_\beta) = \langle \beta \rangle_m$ when $B(t_\beta) \rightarrow 0$, implying that the mechanical state is perfectly transferred to the optical mode (apart from a phase difference). Therefore, the nonclassical features of the generated mechanical state can be directly verified by measuring the properties of the cavity output field.

We calculate the Mandel $Q$ parameter [38], $Q(\alpha, \omega) = \langle (A_{out}^{\text{m.tbl}})^2 \rangle - \langle A_{out}^{\text{m.tbl}} \rangle^2 / \langle A_{out}^{\text{m.tbl}} \rangle^2 - 1$, which is defined for a $m$-PACS $|\alpha, \omega\rangle \equiv \sqrt{|\alpha|^m} |\alpha\rangle_m$, with the normalization constant $N = |m! L_m(|\alpha|^2)|^{-1/2}$, where $L_m(x)$ is the Laguerre polynomial of order $m$. In the present
scheme, we have $m = 1$ and $\alpha = Z(\tau_b)\beta$. A negative value of $Q(\alpha,m)$ represents the sub-Poissonian character of the state, reflecting its non-Gaussian nature. It is known that Gaussian states correspond to Poissonian or super-Poissonian statistics [39]. For $m = 0$, $Q(\alpha,0)$, corresponding to coherent states, while for $\alpha = 0$, $Q(0,m) = -1$. The $Q$ parameter can be calculated more conveniently using the fact that $\langle A^{\text{out}} A^{\text{out}} \rangle = \langle A^{\text{out}} A^{\text{out}} \rangle - 3 \langle A^{\text{out}} A^{\text{out}} \rangle _{1} + 1$, and $\langle A^{\text{out}} A^{\text{out}} \rangle = \langle A^{\text{out}} A^{\text{out}} \rangle _{1} - 1$, and $\langle A^{\text{out}} A^{\text{out}} \rangle = 2B^2 + 8B^2(1-B^2) + 6(1-B^2)^2 \frac{\langle |\alpha|^2 \rangle}{|\alpha|^2}$. For the state $|0\rangle_c,|\alpha,1\rangle_a$, i.e., the state generated after the write pulse and the detection of a single photon being detected [see Fig. 1(b)]. In Fig. 2(a), we show $Q(Z\beta,1)$ vs $|\beta|$ for different values of $B(\tau_b)$. $Q(Z\beta,1)$ well below zero for small values of $|\beta|$ is a clear sign of the sub-Poissonian character of the state, and a small value of $B(\tau_b)$ is preferred for seeing such a nonclassical feature.

Another important property of the mechanical state $|\alpha,1\rangle$ is quadrature squeezing [26], which is a property that a mechanical Fock state [17,18] does not possess. To demonstrate this, we define the quadrature $x_0$ of the cavity output field, $x_0 = (A^{\text{out}} e^{i\theta} + A^{\text{out}} e^{-i\theta}) / 2$, and if its variance $(\Delta x_0)^2 = \langle x_0^2 \rangle - \langle x_0 \rangle^2$ is less than that of the vacuum state, the quadrature $x_0$ of the field is squeezed, implying that the quadrature of the mechanical mode is squeezed. The expression of $(\Delta x_0)^2$ can be obtained,

$$
(\Delta x_0)^2 = \frac{3-2B^2+(1-B^2)(e^{i2\theta}\alpha^2+e^{-i2\theta}\alpha^2)+2|\alpha|^2+|\alpha|^4}{4(1+|\alpha|^2)^2}.
$$

which becomes $(\Delta x_0)^2 = \frac{1}{4}$ for $B = 1$, corresponding to the vacuum state of the cavity output. In Figs. 2(b)–2(d), we display $4(\Delta x_0)^2$ versus some key parameters. It shows that $\beta = \frac{\pi}{2}$ and $B(\tau_b) \rightarrow 0$ ($B_{\text{min}}$ is bounded by $\tau_r \ll \gamma^{-1}$ and $G_r \ll \kappa$) are optimal for observing quadrature squeezing, and considerable squeezing below vacuum has been found in the cavity output field as a result of the nonclassical phonon state.

The effects of residual thermal excitations. We now discuss the effects of the residual thermal excitations $\bar{n}_0 \ll 1$ in the coherent-state-preparation stage. That is to say, we prepare a thermal coherent state (a thermal state displaced by $\bar{n}$ in phase space) with nonzero phonon occupancy [18,32]. Before applying the write pulse, the MR is in the state $\rho_{\text{he,c}} = (1-s)\sum_{n=0}^{\infty} n D(\beta)|n\rangle\langle n| D(\beta)$, with $s = \bar{n}_0(1+\bar{n}_0)$. For $\bar{n}_0 < 0.45$, the MR is most likely (>90%) either in the state $|0\rangle$ or $|1\rangle$. We thus truncate the Fock state basis up to $n = 1$, and $\rho_{\text{he,c}}$ can be approximated as $\rho_{\text{he,c}} \simeq (1-s)|\beta\rangle\langle \beta| + (1-s)\sum n D(\beta)|n\rangle\langle n| D(\beta)$, which leads to the conditional state of the MR (unnormalized) [35],

$$
\rho_{\text{m}}(\tau_b) \approx b^\dagger |\alpha\rangle\langle \alpha| b + s(|\beta|^2 b^\dagger b)|\alpha\rangle\langle \alpha| b + Z^2 b^2 |\alpha\rangle\langle \alpha| b^2
- \beta^* Z b^\dagger |\alpha\rangle\langle b^\dagger - \beta Z b^2 |\alpha\rangle\langle b| b\rangle,
$$

after the write pulse and the detection of a single photon, which contains the component of a two-PACS due to the small probability of the initial state in $|1\rangle_a$. By measuring the cavity output of the readout pulse, we obtain the $Q$ parameter, which takes the form $Q = N_O^{-\frac{1}{2}}[(1+s|\beta|^2)Q_1 + sZ^2 Q_2 - \beta^* Z Q_1 - \beta Z Q_2]$, where $Q_j = \text{tr}[Q|0\rangle_c\langle 0| \otimes b^j |\alpha\rangle\langle \alpha| b^j]$ ( $j = 1,2$), $Q_2 = \text{tr}[Q|0\rangle_c\langle 0| \otimes b^2 |\alpha\rangle\langle \alpha| b^2]$, and $Q_4 = \text{tr}[Q|0\rangle_c\langle 0| \otimes b^4 |\alpha\rangle\langle \alpha| b^4]$. The normalization constant $N_O = 1 + s(|\beta|^2 + Z^2 - \beta^* Z - \beta Z)$ is introduced to keep $Q = 0$ (not 1) for coherent (Fock) states. Figure 3(a) shows the effect of the residual excitations on the $Q$ parameter and no appreciable effect is found in particular for small $|\beta|$. A similar form of $(\Delta x_0)^2$ can be derived [35], which is more sensitive to the residual excitations, as shown in Fig. 3(b). Nevertheless, for small $\bar{n}_0$, significant sub-Poissonian character and squeezing of the state are present, characterizing its nonclassical features. We note that for $|\beta| \rightarrow 0$, we also generate phonon-added thermal states of the MR. Such states also exhibit nonclassical properties as is known from the corresponding studies on photons [40].

In conclusion, we have presented a scheme to generate and detect single-PACS of the mechanical motion in optomechani-
cal systems. It is designed for pulses and combines ground-state cooling, optomechanical parametric down-conversion and beam-splitter interaction, and single-photon detection. Our scheme can also be applied to electromechanical systems and opens promising perspectives for the generation of a series of non-Gaussian states of a mechanical oscillator. While we discussed phonon addition, the process of subtraction can be carried out by using the red-detuned pump and by detecting a single photon [41] for phonons prepared in arbitrary states.
