We study the formation of wrinkles in graphene upon wet transfer onto a hydrophilic target substrate, whereby draining of water appears to play an important role. We are able to control the orientation of the wrinkles by tuning the surface morphology. Wrinkles are absent in flakes transferred to strongly hydrophobic substrates, a further indication of the role of the interaction of water with the substrate in wrinkle formation. The electrical and structural integrity of the graphene is not affected by the wrinkles, as inferred from Raman measurements and electrical conductivity measurements. © 2012 American Institute of Physics.

Graphene has received a lot of attention since its isolation from graphite.1 Although graphene is a 2D crystal, it is so far only found on a substrate, as a membrane with a supporting construction2 or grown at the surface of SiC.3 Therefore, it is considered to be a quasi 2D crystal. Quasi-2D graphene is in general not flat, but has a tendency to form corrugations, including ripples, wrinkles, and bubbles.2,4 The curvature associated with such corrugations is predicted to alter graphene’s electronic and structural properties.5,6 Corrugations are often regarded as undesirable, but they can be exploited for inducing pseudo-magnetic fields,7 creating chemically reactive sites,8 and for specific device applications such as optical lenses.9 Numerical simulations have been done to understand the formation of wrinkles and their impact on graphene.10–13

Wrinkles are commonly found in chemical-vapor-deposition (CVD) grown graphene that is transferred to other substrates.14–17 In CVD, graphene wrinkles are formed at metal step edges due to thermal stress. The morphology of the metal growth surface can still be seen after transfer. In many cases, additional wrinkles, ripples, and bubbles are formed upon transfer. Exfoliated graphene mostly conforms to the corrugations of the underlying substrate,18 although small additional wrinkles can be observed in a scanning tunneling microscope.19

In this work, we study the formation of wrinkles in graphene during the so-called wedging transfer process, a water-based transfer process.20 We give insight in the driving forces for wrinkle formation and suggest different routes to control the wrinkle orientation and abundance, or to eliminate wrinkles altogether. We also examine to what extent the electronic and structural integrity of graphene is preserved upon wrinkle formation.

The wrinkle formation can be easily seen with an optical microscope, as illustrated for a graphitic flake in Fig. 1 (the entire process is carried out under ambient conditions). Graphitic flakes of varying thicknesses are prepared by mechanical exfoliation of graphite (NGS Naturgraphit GmbH) on Si substrates with a 285 nm thermal oxide. A hydrophobic polymer film covers the substrate (Fig. 1(a)), and is “wedged off” the substrate by intercalation of water (Fig. 1(b)), along with the graphitic flakes. As a result, the film with the flakes is floating on top of the water surface (Fig. 1(c)).

As the thickness of a graphitic sheet is reduced, the wrinkles increase in density and decrease in height (Fig. 2). This can be expected given the lower stiffness of thinner sheets. Fig. 2(a) shows a graphitic flake with pieces of different optical contrasts, corresponding to different sheet thicknesses (the lower the contrast, the thinner the flake). Figs. 2(b)–2(e) show atomic force microscopy (AFM) images taken on the respective parts of the flake, as indicated. The mean wrinkle height is (c) 12 ± 7.9 nm, (d) 7.6 ± 3.4 nm, and (e) 4.4 ± 1.5 nm, respectively.21

The highest density and lowest height of the wrinkles is obtained for single-layer graphene (SLG). Fig. 3 shows an AFM image of a SLG flake (a) before and (b) after transfer, showing no wrinkles before transfer and a large wrinkle density afterwards.

The Raman spectrum of this SLG flake taken after transfer (Fig. 3(c), wrinkled) is very similar to that taken before transfer (pristine). It is characteristic of single layer graphene,22 and there is no detectable defect-related D band near ~1350 cm⁻¹. There is no evidence for degradation of the structural integrity of SLG upon wedging transfer.

Next, we perform electrical transport measurements in order to estimate the charge-carrier mobility and the mean-free path. We contact several wrinkled SLG flakes with 10/60 nm Cr/Au electrodes using e-beam lithography. A typical device is shown in the inset of Fig. 3(d). In a four-point field effect transistor (FET) geometry, we measure the resistance as a function of applied back-gate voltage, Fig. 3(d). The measurement is done in high vacuum (~10⁻⁵ mbar) at room temperature. The flake geometries are

irregular. For estimating the conductivity from the conductance, we choose an aspect ratio such that the mobility values obtained are an underestimate. The charge-carrier density is calculated by applying the parallel plate capacitor model, taking the usual conversion factor for 285 nm SiO$_2$ of $7 \times 10^{10}$ cm$^2$ V$^{-1}$ s$^{-1}$. From the slope in Fig. 3(d), we calculate a hole mobility of $3800$ cm$^2$ V$^{-1}$ s$^{-1}$ and an electron mobility of $4400$ cm$^2$ V$^{-1}$ s$^{-1}$. These are typical values found for SLG on SiO$_2$. We have no indication that the wrinkles degraded the mobility. This is not surprising given that the mean free path is around $\sim 20$ nm and the wrinkle-to-wrinkle distance is $\sim 1$ nm.

Fig. 4(a) shows an AFM height profile of a typical wrinkle. The mean height along the wrinkle is $H = 3.3 \pm 0.4$ nm with a mean full width at half maximum (FWHM) of $W < 6.8 \pm 2.2$ nm (due to the width of the AFM tip, the width measurement is an upper bound). These dimensions are well in the regime of $H^2/Wa > 1$ ($a = 0.24$ nm is the graphene lattice constant), where the pseudo-magnetic field from the corrugations is predicted to be large enough to induce a zero-energy Landau level.

In Fig. 4(b), we demonstrate that using the morphology of the substrate we are able to control the orientation of the wrinkles to a certain degree. We have fabricated 1 $\mu$m spaced metal strips of 200 nm wide and 55 nm high. SLG is transferred onto these periodic structures, and is partially suspended between the top edge of the step edges and the substrate, as can be seen in Fig. 4(b). It shows that there is room for water to evacuate near the steps. Wrinkles form in the direction perpendicular to the steps (Fig. 4(c)), presumably so that water can be evacuated towards the steps, and outwards from there. In this way, we demonstrate the possibility to align nm sized wrinkles in graphene. We propose that milling small trenches ($<50$ nm width) in a substrate would yield a similar result, if graphene can freely suspend over these trenches. This could be used to study electronic transport across multiple aligned wrinkles.

The density of wrinkles in graphene may also be controlled by using other polymers for the transfer or by performing the transfer at different temperatures.
local pseudo-magnetic fields. The curvature also increases the magnetic field, the angle between field and flake will vary. In the presence of a density and orientation of the wrinkles. This could be useful before transfer. It is possible to control to a certain extent the mobility which is comparable to those found related D-peak in this wrinkled graphene, and transport measurements show mobilities comparable to those found in one-dimensional patterns along the wrinkles.

We thank Gilles Buchs and Bart van der Linden for assistance with the Raman measurements, and Andrea Ferrari, Amelia Barrero, Xing Lan Liu, and Stijn Goossens for useful discussions. This work is part of the research program of the Foundation for Fundamental Research on Matter (FOM), which is part of the Netherlands Organization for Scientific Research (NWO).

speculate that the wrinkle density and height depend not only on the polymer viscoelastic properties but also on the polymer film thickness and the polymer concentration in the solution the substrate is dipped in to cover it with the polymer.

Finally, we show that wrinkle formation can be prevented altogether by transferring flakes onto hydrophobic substrates, as shown in Fig. 4(d) for a SLG flake. To render the surface hydrophobic, it was functionalized with a fluoralkane molecule (CF3( CF2)4 (CH2)2 SiCl3). This observation supports the hypothesis that water plays a key role in wrinkle formation during wedging transfer.

In summary, we find that wet transfer of graphene onto commonly used hydrophilic substrates induces wrinkles in graphene. Raman measurements show no detectable defect-related D-peak in this wrinkled graphene, and transport measurements show mobilities comparable to those found before transfer. It is possible to control to a certain extent the density and orientation of the wrinkles. This could be useful for studying electronic transport across a controlled number of (aligned) wrinkles. It also opens up the possibility to explore a number of other experiments. In the presence of a magnetic field, the angle between field and flake will vary on a nm length scale. In addition, the curvature induces local pseudo-magnetic fields. The curvature also increases chemical reactivity which can be exploited to chemically bind atoms or molecules in one-dimensional patterns along the wrinkles.
